DISEASES OF THE THROAT.
—

BRONCHOCELE.

THE disease to which I shall next direct your attention, gentlemen, having now finished the consideration of diseases of the cranium, is situated in the neck, outside the air-tubes—in the gland called *thyroid*.

Etymology.—This disease is called *bronchocele*, from *βρογχος*—the windpipe; and the substantive of which we make so much use, *κηλη*—a tumor. The French call it *goitre*; and it is supposed that this is a corruption of the Latin word *guttur*—the throat.

Symptoms.—The symptoms of the disease, however, are a swelling in the front of the neck, in the situation of the thyroid gland, and produced, in fact, by an enlargement of that gland. No disease would be called *bronchocele*, although a swelling in the neck, unless it were the result of an enlargement of the thyroid gland. This tumor is for the most part soft, and neither painful nor tender: it is neither painful when left to itself, nor is it so when touched; and therefore it is not tender. Occasionally, however, it is very hard in some portions; although it is usually soft in almost every part, yet occasionally you find it hard in some one part—of cartilaginous, and, indeed, sometimes of bony hardness. It may attain a large size, and of course it may be very small;

it may, in fact, be merely a general fulness of the gland, or a slight general enlargement; but very frequently you find it is enlarged chiefly, or almost entirely, in the centre, or on one side particularly; and from being at the beginning a slight fulness of only one lobe of the thyroid gland, it may attain so enormous a size as to hang down to the knees. Foderè, in his Treatise on the disease, mentions an instance of a tumor which weighed seven or eight pounds; and Alibert, the writer whose representation of diseases on the skin I shewed you, mentions a tumor, occurring in a man 38 years of age, which reached to the middle of the chest, was as large as a pumpkin, and looked like a pelican's pouch. There is also one mentioned as existing in a female upwards of 60 years of age: it extended from ear to ear, and descended below the mammæ, impeding deglutition and respiration, and it pressed considerably on the meatus auditorius, so as to close it up. A German author mentions an instance of a goitre descending to the knees.

Females most liable to it—seldom commences before eight years of age.—This disease affects females more frequently than males, and usually it does not begin before the individual has attained eight or ten years of age: there are, however, exceptions to this. A physician, in the London Medical Repository, mentions a child, in Derbyshire, who was born with one of considerable size. At different times, when I have been in Switzerland, I have made inquiry about it of the country people and of my guides; and one old peasant told me, that he knew an infant who was born with a goitre; and I myself saw one in a little boy only four years of age. However, the answer I usually received was that the disease seldom appeared before six years of age, nearly agreeing with what is usually stated by authors. Authors state, that in gene

ral it does not begin before the eighth or tenth year; and, indeed, I was told that, not only that, but even cretinism—the idiotcy of the country, which I formerly spoke of—did not begin in early childhood. Some of these people have an idea (and they told me, and wished me to believe it) that a child has a goitre, or is a cretin, if either of the parents were drunk at the moment the little fellow was begot. They ascribe it to that; not, however, in every case.

However, as the disease is certainly seen in children, and they are sometimes born with it, and frequently the parents have goitres, it may be hereditary; but although both parents may have goitres, yet, just as we observe with respect to other diseases, it does not follow that the progeny must have goitres. A case has been mentioned to me of a goitrous father and mother who had begotten between them five children, all of whom were goitrous—in a state of cretinism; and of another pair, both goitrous, who had four children with goitre, and one, twenty-two years of age, who was neither goitrous nor idiotic; in fact, he said she was tall and *gentil*—*très gentil*.

Frequently accompanies Cretinism.—This disease very frequently accompanies cretinism. When you see an individual with a large head, an ace of spade nose, the eyes a mere slit, perhaps deaf and dumb, and imbecile, it is very common to see the thyroid gland enlarged—to see bronchoecle exist; and it is asserted that if people, both having goitres, marry, and one of their children having a goitre marry another with a goitre, that their offspring—third generation—are sure to be something worse than goitrous—to be cretins—to be idiotic. This is asserted; but I do not know its truth from any observations of my own.

Tendency to increase.—When the disease has begun, it usually increases; but occasionally it makes a stop—does not, at a certain period of life, increase any more; and I have fancied that it has sometimes appeared to shrink in old age.

May destroy Life by Pressure.—Bronchoecle may destroy life by pressure on the neighbouring parts; and Dr. Baillie says that he saw one or two cases in which death took place from pressure on the œsophagus and trachea. I have frequently seen it affect the voice so that a person spoke in a hoarse, croaked tone, with a sort of hissing sound, such as is produced when the trachea is pressed.

Brutes liable to it.—The disease is not entirely confined to the human subject, but cattle also and dogs have it. It is very common for it to be less during the winter,

and to increase again during the summer. It is said usually to begin in one lobe only of the thyroid gland.

Appearance and Contents.—You will find its external appearance sometimes uniform and sometimes knotty; and on cutting into the tumor, you will find cells of all sizes, and with contents of various consistency. Sometimes the contents are found gelatinous, and sometimes soft. Sometimes one particular part is cartilaginous, or even ossified, and you will see a quantity of calcareous matter. You will see a variety of appearances in different parts of the same tumor. There is a representation of the disease in Dr. Baillie's work. Occasionally the tumor suppurates, and sometimes disappears spontaneously. I need not say that the blood-vessels of the part are found very much enlarged.

Prevalence in various Parts of the World.—Now this is a disease which is seen in various parts of the globe; in all latitudes—in hot latitudes and in cold latitudes. It is seen in England, France, Spain, Switzerland, Germany, China, Tartary, Bengal, and the Island of Sumatra. Mungo Park says that he saw it in the negroes of Barbary. It is seen in Spanish America, and again in North America.

Causes.—Some have ascribed it to the cold; but as it occurs among the negroes in Barbary, and also at Bengal, it cannot be owing to the cold. Some have ascribed it to the snow-water; but there is no snow either in Barbary or Bengal; and, on the other hand, the disease is unknown in Greenland and Lapland, where there is little else than snow-water, and where the weather is very sharp. It appears, however, dependent, I think, in some measure upon the water; for the waters in the rivers and lakes of Switzerland are always bad, and are drunk only by the poor and ignorant; and those who drink them heartily are, for the most part, sure to have the disease. Those who are above the very lowest, the most abject class, do not drink the waters either of the rivers or lakes, but the most ignorant people do; and I believe I mentioned before, that I have seen them drinking water the colour of ink. I had an intelligent guide in Switzerland, in 1826, and he told me that, beyond all doubt, this water produced it; but those who drank spring or snow-water, which did not run along a bed of lime, escaped; and nearly all escaped who drank cascade water. He said that the bad water usually took about a year to produce the disease; but the instant the bad water in his neighbourhood was drunk by those unaccustomed to it, they found unpleasant effects; and sometimes, he said, these were prevented by putting a bit of ice or snow

to it. Now Capt. Franklin, in his *Journal of a Voyage to the Polar Sea*, which is situated at a great distance from Switzerland, makes an observation perfectly agreeing with the account which this man gave me. Capt. Franklin says, that at Edmonton, on the banks of the Saskatchewan river, goitre is very common; that it is certain, goitre effects only the drinkers of this water; and that, in its worst state, the disease is confined almost entirely to the half-breed women and children who are always resident in the Fort, and make use of the river water, drawn, in the winter, through a hole made in the ice: whereas the men, from being often from home on journies, and using snow-water, are less affected with goitre; and when they are at home in the winter, if signs of goitre come on, their annual summer visit to the coast presently cures them. He says, the natives who confine themselves to snow-water in the winter, or some of the small rivulets which flow through the plains in the summer, are exempt from the disease. A residence of one year at Edmonton, where the water is so bad, is sufficient to render a family bronchoceleous. He says that many of the goitres acquire a large size, and burnt sponge has been tried, and found to remove the disease, but drinking the water again renews it. A great proportion of the children who have goitres, he says, are born idiots, with large heads and other distinguishing marks of cretins; but he could not learn whether it was necessary that both parents should have goitres to produce cretin children.

Another year that I was in Switzerland, passing along a valley near the lake of Valtelline, the guide told me that in one of the populous villages there was no spring, and the inhabitants are therefore obliged to drink the water of the river, which is so bad that goitre prevails there very much indeed; but in another village there are plenty of springs, and nobody there thinks of drinking any water except that from the springs, and no one there has goitre. He also added, that where there is much goitre they are all Catholics, whereas in the village where there are plenty of springs, the inhabitants are Protestants. This is rather an important remark, because it is a very striking circumstance that, on many parts of the continent, the Protestant districts are much cleaner and more healthy than the Catholic districts. More frequently than not you can tell the Catholic districts by merely looking round and observing the state of the peasantry, without asking a single question. The Catholics spend so very much time in praying, that they are dirty in their

persons, negligent altogether, not at all industrious; whereas the Protestants are very clean, not spending so much time in church exercises, and they are much better off altogether. No one who has travelled much can doubt the truth of this remark; and in one of the villages alluded to the people were much worse off than in the other. Now it is important to know this, because I shall have to mention, that the worse people are off, the more subject are they to the disease when the causes are applied.

The nature of the water which produces this disease is not well known, but it is in all probability mineral; I presume it to be so, as the water contains so much lime, but will not assert it. Captain Franklin says that those inhabitants who reside 60 miles nearer the source of the river than Edmonton, are said to be more severely affected than those at Edmonton; and he says goitre is unknown at a distance from the river, where nothing but snow-water is drank for nine months in the year; and he adds, that still farther from the source than Edmonton, where the water is still turbid, the disease is unknown. It certainly appears connected with the water, and it appears to arise from some impregnation which the water has near its source, and which it loses as it goes along. At Edmonton too, Captain Franklin tells us, that the river is clear excepting from the month of May to July; and that the distance from the rocks and mountains is 130 miles. The neighbouring plain is alluvial, and the soil calcareous, with many fragments of magnesian lime-stone. In Switzerland it would not appear to be originally in the water at its source, because the springs and cascades do not produce it; on the contrary, it is the water that runs along beds, and is found in lakes, that appears to give rise to it. Persons on the mountains are rarely affected, and those who remove from the valleys and places where it prevails, to the mountains, find the tumor in some degree alleviated, and after a great length of time the disease is known to cease altogether. The disease prevails much more in valleys with high mountains around them than elsewhere, such as you see in Switzerland, and perhaps in those which are most exposed to the east and south winds.

Whatever may be the cause of the affection, it is found to prevail most where the air is worst—where the mountains cause the air to be pent up, and where the persons are badly off. It prevails in a particular valley in Switzerland most frightfully, and there the people are the worst off; for there you see more poverty and wretchedness than in almost any other

part; the inhabitants are dirty, and badly fed. In the countries where it is prevalent the people have a dirty brown look, and appear withered, as if they were in premature old age. It seems that the causes which produce the disease are those which poison the habit generally, and render it more liable to be affected by the causes of this particular disease. They have an aguish or malaria sort of look; yet you sometimes have it where there is no ague, and you have ague where you do not meet with this disease. Any circumstance which throws the body out of health may predispose to this disease. The particular circumstance of the patient having a withered look may not be immediately connected with bronchocele; but the causes of the withered look may impair the constitution, and render the person constantly liable to become goitrous. My own guide told me, that where the inhabitants were dirtiest, and the worst fed, they were most subject to the disease. Dr. Good says that it appears in Derbyshire among the poor only; I suppose he means chiefly. He ascribes it to oat cake; but it is eaten in other parts of England with no such effect.

Treatment.—With regard to the treatment of the disease, certainly the patient should desist from drinking any water which may be suspected to be the cause of it. Burnt sponge is unquestionably useful in it; and many practitioners say that they have seen cases cured by it. I presume there can be no doubt that it possesses a remedial power over the disease; and some unite it with sulphur.

The most efficient remedy, however, by far, is iodine; and it may be employed externally or internally. I have myself cured many cases of bronchocele, some of them where the tumor was rather large, with this remedy. It may be employed in the form of iodine itself, or it may be united with hydriodate of potassa, and that perhaps is the best way of administering it. In regard to the quantity there is no rule for the dose, for it produces two effects, constitutional and local. The constitutional effects are emaciation, morbid irritability of body, quickness of pulse, palpitation, absorption of particular parts, it is said, more especially those connected with the succeeding generation—the mammae of women, and testes of men; it takes away likewise the appetite, and is more or less injurious to the body at large. But besides that, it is a very acrid substance, and therefore, like any other acrid substance taken into the stomach, it will produce vomiting and gastritis, and even ulceration; and when it passes the stomach, it may produce diarrhoea and more or less inflammation of the mucous mem-

brane of the intestines. Now it affects the stomach and intestines immediately, simply as a corrosive agent; and this may arise in one person from a small quantity, when it will not occur in another from a large quantity. You never know beforehand the disposition of the patient in regard to it, and therefore it is always best to begin with a small dose. There can be no impropriety, as the disease is chronic, in delaying an efficient dose for some time. You may therefore begin with five minims of the saturated tincture, and if no unpleasant effect be produced, it may be increased a drop every dose, or every other dose. I have gone so far as to give 100 minims for every dose, but a great number of persons will not bear above 20 or 30 minims. Patients complain of heat of the stomach; and if you begin gradually, and inquire of the patient whether there is any burning sensation, or heat of the stomach, or any griping, you never need run the risk of doing mischief from its local effects. When a person begins to feel a dose, such as 15 or 20 minims, I have been told that diarrhoea took place—even griping and bleeding, it is such a corrosive substance; and if a quantity be taken into the stomach, the mucous membrane will soon be in a state of erosion.

As to the other salt, hydriodate of potassa, there is scarcely any rule for the dose, but it may be given in larger doses than the other. If you mix a drachm with an ounce of distilled water, you may begin with ten or fifteen minims, and increase the dose to a great amount. There are two or three men at this moment, whom some gentlemen present have seen at St. Thomas's Hospital, who are taking two drachms of the salt at a time; and there can be no doubt that the medicine is good, because Dr. Burton has analysed it very carefully. The article is often adulterated, and lime has been found in it; but care has been taken to have a good article, and that which is now being taken is known to be a pure salt; and I recollect at this moment two men who are taking two drachms for a dose, and a woman who is taking one drachm for a dose three times a day, diluted with ten or fifteen ounces of distilled water. There is no rule for any dose of medicine that is applicable to all cases. It has been thought by some, that it would be better to give iodine itself and this salt together. Some persons always find fault with others who are energetic, or employ remedies in an efficient manner; but there is no reason because you are energetic, and employ them *efficiently*, that you should employ them *rashly*. There is no occasion to do a patient harm, and no occasion to run any risk.

With respect to the length of time during

which the remedy may be taken, I have been obliged in bronchocele to give iodine a whole year before the disease was cured. Seeing the disease was lessened, I persevered, and have gone on for twelve months, and, indeed, above that time—I think in one case fourteen or sixteen months, before the disease went away. That was the largest case of bronchocele that I ever cured. I never saw any unpleasant constitutional effect, though no doubt such effects will occur, because they have been mentioned by authors; but I think if you see the patient frequently, and make proper inquiries at every visit, in general such unpleasant effects can hardly occur—at least I think not. Now and then you may be taken by surprise with it, as is the case with every remedy: it may suddenly act: but in general, when a remedy appears suddenly to act, it has been continued some time after its effects have begun; and if it had been watched carefully, and left off the moment it commenced its action on the body, no such effects would have ensued. I cannot but think, in cases where a remedy has seemed to act suddenly, with the exception of digitalis, that in the greater number of instances it has begun to act moderately, and then been continued without diminution; because had it been omitted, the moment the effect began the slight effect would gradually have ceased. I am not aware of ever having done mischief with iodine.

It is well to apply the remedy externally as well as internally; and you make an ointment by putting a drachm, or even two drachms of the hydriodate of potassa to an ounce of grease. Of course the skin differs like the inside, and the constitution at large; and what produces merely an irritation in one part, will produce a diffused rash in another. It is well to use half a drachm or a drachm at first, if the person have a fine skin; and then, if no ill effect be produced, you can increase it. Of course, it is absurd to apply it so as to irritate the skin; the patient cannot bear rubbing then; and if inflammation begin, it must go down before you can apply it again, and you lose so much time. We shall see, when I speak of diseases of the abdomen, how much good is effected in the same way as in bronchocele by the exhibition of this medicine. It has been supposed that the good effects of burnt sponge are ascribable to the iodine which sponge contains.

Besides burnt sponge and iodine some recommend carbonate of soda, some conium, and some leeches. If the part fall into an inflammatory state, leeches may be useful; and if inflammation occur, the iodine should be suspended, and common anti-

phlogistic remedies resorted to till the effect has ceased, and then it should be had recourse to again. Mercury, internally and externally, has been useful, and the two may be combined. I have seen the disease give way to the two, but I can hardly say how much good was ascribable to each.

Pressure has been said to be useful, but it is awkward to make pressure, on account of the trachea and œsophagus. There can be no doubt that a seton in this disease is an efficient remedy. There are very many cases of this disease on record which have yielded to a seton placed in the skin over the tumor.

The disease has been treated surgically as well as medically. Some surgeons have tied the vessels of the tumor with good effect, but this is a point on which I must not dwell. I have only to do with this disease as it is to be treated by medicine, but I may mention that Mr. Thomas Blizard, formerly an able surgeon at the London Hospital, tied the vessels, but death took place from secondary hæmorrhage; however, in one week the tumor decreased in size one third. Walther, the celebrated surgeon, tied the left inferior thyroideal artery, and the tumor diminished so much that at the end of fourteen days he took up the right superior thyroideal artery: no inconvenience was felt, and the tumor speedily almost entirely disappeared. A surgeon in this country, Mr. Coates, tied the artery on the left side only, and cured the complaint. However, some surgeons have been bolder still; and Dr. Hedenus, of Dresden, with whose son I was acquainted, extirpated the gland in six cases, in one of which it was as large as a skittle-ball. The whole of the cases were successful. Foderé mentions the case of a barber who cut one away from his wife. This was a lucky hit, for he would probably kill the next woman on whom he operated. Two unsuccessful cases of extirpation are said to have occurred to Mr. Gooch. Dupuytren, the celebrated French surgeon, removed a tumor after having first tied the arteries: only a few spoonsful of blood were lost, but the operation was very long: much suffering took place, and the patient died in thirty hours. In several cases the operation has been found so hazardous, and altogether so difficult, that the surgeon has been obliged to desist in the midst. Desault is said to have removed half a one with success.

The chief treatment, however, is by iodine internally, and by means of a seton; but you are not to suppose that either of these will cure every case. I have seen the tumor so hard that it was quite

absurd to suppose any thing was capable of removing it. When it is cartilaginous, or ossified to a great extent, I should think it in vain to give iodine, or apply a seton. Respecting extirpation, I may mention that I find a note in Frazer's Journal, stating that in no part of the world has the whole tumor been extirpated. There can, however, be no doubt of the fact, for persons have shewn that the tumor has been extirpated by the scars in the neck left after the operation.

Parotitis.

The next disease of which I shall speak is one situated in the glands in the neighbourhood of the thyroid, but a little higher. This is entirely a medical disease, and I believe the surgeon never applies his art to it. The last I spoke of is disputed territory—surgeons take it, and physicians take it—but this, the mumps, is, I believe, strictly medical. This is called, as it is an inflammation of the parotid glands, *parotitis*, or, in the language of Cullen, *cynanche parotidea*.

It is right I should mention that Dr. Cullen makes five kinds of *cynanche*.—The definition of the whole is, “pyrexia, frequently of the typhoid type; redness and pain of the fauces; deglutition and respiration difficult, with a sense of constriction; narrowness in the throat.” This is his general definition of *cynanche*.

Now the first of the five kinds of this general nature is inflammation of the parotid glands. I think it better to drop the word “*cynanche*,” and not consider the different parts of *cynanche* as varieties of one general affection; but I shall speak particularly of inflammation of the parotids, inflammation of the tonsils, and so on; and I presume that in a few years the word *cynanche* will be dropped, and we shall speak only of diseases of one part or another.

Symptoms.—To speak of *parotidea* or *parotitis*, or, in plain language, the mumps, this is a swelling of one or both parotid glands, attended with an increase of heat in the part, extending to the submaxillary and sublingual glands, and affecting the rest of the salivary glands. The disease is attended by slight feverishness, slight pyrexia, and lasts in general three or four days, sometimes longer. It is sometimes followed by inflammation of the testicles or breasts, which some call *testitis* and *mammitis*. Certainly either is a much better name than *hernia humoralis*, which caused great confusion, because it has nothing to do with what we understand by *hernia*. However, inflammation of the parotid or salivary glands is sometimes followed by inflammation of

the testes or breasts, and then this is sometimes followed by phrenitis; and when a testicle has been so inflamed, it frequently afterwards shrinks, wastes away, suppurates, atrophies, and nothing is left but the membranes, the albuginea and tunica vaginalis.

Usually occurs but once.—This disease occurs usually but once during life, and it is said to be contagious. It certainly is sometimes sporadic; you see single cases; but frequently it is epidemic; it prevails in a boy's school all at once throughout, and it prevails in several schools in the same neighbourhood, and many believe it to be contagious. I really do not know whether it is so or no.

Usual periods of occurrence.—It occurs most frequently from seven to fifteen years of age, sometimes later. Now and then you will see it in young men, but most frequently it occurs at the time I have stated.

Treatment.—There is nothing particular required for it in the way of treatment: you have only to apply moderate warmth, keep the patient quiet, make him abstain from ordinary nourishment and stimuli, give him a mild aperient, and the disease, for the most part, goes away after a time. It is very rarely that suppuration takes place. I have seen suppuration, but I presume it was an accidental circumstance, from the inflammation extending to the cellular membrane. I should not recommend cold to be applied, because the disease has a tendency to metastasis, at least to the testicles and breasts when it ceases, and one would suppose that if you cause it to cease suddenly there is a greater probability of such inflammation occurring.

As to inflammation of a testicle, that is not in itself a dangerous thing: it is only sharp and painful, yet it is thought to be a serious thing. I believe, however, there is no great harm if one should be lost, because the other does double work. But there is something more dangerous, and that is the liability to phrenitis. Phrenitis sometimes takes place when inflammation of the testicle ceases: sometimes the inflammation in the brain may occur when the mumps cease, but more frequently than not inflammation of the breast or testicle occurs first, and then phrenitis supervenes.

If the case be severe, you must treat it more antiphlogistically still, by means of leeches and purgatives, but in general nothing more is required.

ON VASCULAR TUMORS.

To the Editor of the Medical Gazette.

SIR,

HAVING had much opportunity of seeing and examining the diseases which are described in the following paper, and having employed, or witnessed the employment of, the various remedies which have been proposed for their cure, I am induced to offer the fruits of that experience to my medical brethren. That they may be useful in their tendency to point out that kind of treatment best adapted to the peculiar case, is the object for which they are published.

I am, sir,

Your obedient servant,

BENJAMIN PHILLIPS.

17, Wimpole-street, March 26, 1833.

The diseases upon which I am about to make some remarks are frequent in their occurrence, and important in their consequences; they are occasioned by a certain state of the vascular system, not well defined, and have received various denominations.

I allude to those vascular tumors produced by either a development of a congeries of new vessels, arterial as well as venous, or by the enlargement and varicose condition of some already existing in a capillary condition.

These tumors, then, appear to be formed by a dilatation of the already existing capillary vessels, either arteries or veins, or by the development of a new series, and to be a consequence of irritation of a feeble, dull, heavy, latent character, scarcely superior in degree to that necessary for the healthy exercise of organic action,—almost analogous to that necessary to nutrition, but which, instead of resulting in a regular development of the proper tissue of the organ, as in hypertrophy, determines the irregular development of a new tissue. Perhaps no subject is more worthy of the attentive consideration of the physiologist than the study of the formation and development of these and similar diseases; by them he might discover the formation of the first vestiges of organization. What subject of meditation—what source of discoveries can be more interesting than the contemplation of these curious phenomena?

This disease appears to affect indif-

ferently the arterial as well as venous vessels, which soon acquire an extraordinary volume. These vessels appear interrupted at many points, and in lines parallel to their axes, producing a cellular character, so that sometimes for a considerable extent they have an appearance which is not unlike that of the colon. They manifestly maintain their communication with the system to which they belong, and preserve all its properties. When arterial, the circulation in them is energetic; and when they are opened, the blood escapes rapidly by an intermitting jet.

These tumors have been variously designated, according to their supposed mode of production, or their presumed organization; *nerus maternus*, in consequence of a presumption that they were produced in the child by certain unpleasant sensations occasioned in the mother during her pregnancy*; *aneurism by anastomosis*, *bleeding fungus*, *fungus hamatodes*, *erectile tumors*, and so on.

Erectile tumor is the name which has been applied to them by MM. Dupuytren and Rullier, in consequence of the extreme similarity of their structure to those spongy tissues existing naturally in the penis, the clitoris, the nipple, and other situations, and which they had already distinguished by that term; these tumors, however, require for their erection a much more energetic stimulus than the erectile tissues existing naturally in the economy.

They are of a brownish, reddish, bluish, livid, or blackish colour, are more or less projecting, but easily reducible by pressure; they are sometimes circumscribed, at other times more diffused, sending processes or prolongations to a distance from the tumor. The colour, however, varies much, according to whether they be cutaneous or subcutaneous, superficial or deep-seated.

Before I proceed further, I may state distinctly that I mean here to speak only of those tumors which are composed simply of a vascular net work de-

* Klein speaks of a woman who, at the eighth month of her gestation, saw her husband very ill used, having the left side of his face blackened by contusions which he had received in the affray. This woman was much frightened, and was delivered of a child who had the same portion of his face covered with a blue excrescence, the production of which was, of course, referred by the mother to that circumstance, but which was simply an erectile tissue, which extended to the eye-lid, and prevented the child from opening its eye.

veloped in excess, and which do not, during any period of their existence, contain any matter, except blood-vessels interlaced like the substance of the placenta or spleen, and in which we never find either fibrous, scirrhus, or cerebri-form substance; and this is their wide and distinct demarcation from medullary fungus.

These tumors, which I have thus described, are purely local diseases, and always curable when placed in situations where they can be entirely removed; but if the smallest portion remain, it suffices for their reproduction; whilst those of a medullary character, after the immediate period of their development, are incurable in the present state of our knowledge.

In a few words, then, erectile tumors, which is the name by which I shall designate them, are simple in their organization, being vascular only, while the malignant disease is complicated in this way—the capillary vessels ramify in a soft, pulpy, yellowish, cerebri-form matter.

The differences most frequently observed in the organization of these productions are as follow:—Sometimes the arterial, and sometimes the venous system, shall be most developed; sometimes the tumor is surrounded by a fibrous membrane or capsule, at others it is perfectly free and unconfined; sometimes a central cellular cavity exists, with which the vessels communicate, and which always contains blood in a semifluid state; at others no cell shall be present. These varieties which exist in the organization of such tumors will serve to explain, to a certain extent, the discrepancies which are observable in the different descriptions of them given by authors.

My observations do not enable me to state decidedly whether or not these peculiarities cause any difference in the nature or progress of the tumor; but I am inclined to think that it is those only which are enclosed in a capsule which occasionally remain for many years stationary.

In the first kind of erectile tumor, if we carefully inject the arteries passing to these tumors, we find developed a well-marked vascular net-work, and we shall not find the slightest extravasation of the injected matter. An injection pushed into the veins of this species does not arrive at the tumor; in the venous

kind the opposite holds good. In either species, if a central cavity exist, the injection will distend it.

This disease is most frequently congenital; occasionally, however, it is accidentally produced; often without known cause; sometimes succeeding to external violence, such as repeated pressure, contusion, or puncture. All ages and constitutions are subject to it, but it appears to attack in preference young persons, in whom the fibre is lax. When it attacks the old, the prognosis is much more unfavourable. If, however, the origin of these congenital tumors be placed in the deepest obscurity, the production of the disease in after life is perhaps not better known, for contusions and punctures are far from explaining the birth of a new organ. The vulgar opinion, which refers these alterations of the skin to moral affections produced in the mother during her pregnancy, is now nearly exploded by medical men. Chaussier has remarked, that they were most frequent in those infants whose mothers were subject to diseases of the skin; and this opinion has been confirmed by a great number of facts observed since his time.

They sometimes remain stationary for years, occasioning neither pain nor constraint, and without occasioning tumefaction; sometimes they do not increase until the approach of puberty; at other times, after being elevated into a middle-sized tumor, they remain so, taking no further increase during the life of the patient; but usually the tumefaction increases even from the earliest age, and makes rapid and dangerous progress, the tumor becoming extended beneath the teguments, and making a greater or less circumferential projection.

Dupuytren saw a man who had one of these tumors upon his head, exactly upon a point which was compressed by his hat; this man, in consequence, constantly carried his hat under his arm. One day, being excited at something, he suddenly put his hat on his head, without regard to the tumor, which was injured by the violence, and bled so profusely as to require immediate removal.

I know a man of thirty who presents such a tumor, its posterior border resting upon the anterior margin of the latissimus dorsi muscle, and extending nearly to the umbilicus. It had increased between his seventeenth and

twentieth years from the size of a sixpence to the size of fifteen or sixteen inches in circumference; for the last ten years it has not increased, neither does it affect his general health.

These tumors may be developed in any of our tissues; most frequently, however, they are observed in the skin, the subcutaneous cellular tissue, and the extremities of the long bones.

The division which was made by Mr. Wardrop in these tumors appears to be the best, and also to be a sufficient distinction for general purposes. He divided them into cutaneous and subcutaneous. The cutaneous variety, by which I mean those which primarily affect the skin, is usually a congenital disease; it appears at first in the form of a flat, reddish, violet spot, about the size of a flea bite, of a more or less intense red colour, according to the influence of those causes by which the circulation of the blood may be accelerated, and to its arterial or venous character. The tumefaction of the skin is usually very inconsiderable, and the disease appears to affect especially its reticulated portion, the blood-vessels of which acquire a considerable development. This species is most common about the head, on the forehead, at the root of the nose, on the eye-lids, on the lips, and the lobe of the ear; they also appear not unfrequently on the shoulder, and on the sternum.

No difficulty of any considerable extent can be experienced in the diagnosis of this disease, when it is cutaneous. The only affections to which it may bear a similarity, are those pigmentary depositions in the skin which have obtained the name of pigmentary *nævus* or *spili*; and here the demarcation is sufficiently distinct, for the latter never have any tendency to change during vascular excitement, or to occasion ulceration of the skin. But we have not the same facility when the disease is subcutaneous, and especially when it has its seat in the long bones.

In these cases, if we can discover no pulsation in the tumor, it may be extremely difficult to determine whether or not the disease be medullary fungus; yet the absence of lancinating pains, the uncertain fluctuation which is developed by the alternating pressure of the fingers, the diminution of its volume under the influence of compressing agents, the fresh colour of the patient, and the non-existence of the symptoms

by which a cancerous cachexia is characterized, are so many circumstances which may serve to conduct us to a true knowledge of the disease.

The great differences between the medullary fungus and erectile tumors are, first, that the latter are usually congenital, the former perhaps never: compression, which has no effect on the former, considerably diminishes the volume of the latter. In the latter we generally find pulsation or trembling; it is enlarged at the approach of menstruation: this never occurs in the former. The latter usually has its seat in the skin, or subcutaneous cellular tissue; the former attacks all tissues and all viscera. The former consists of a pulpy cerebriform matter; the latter is composed of blood-vessels and cells, constituting an entirely local disease, the entire extirpation of which effects a cure. The former, very soon after its deposition, becomes a constitutional disease, which, if we can remove from the exterior, we shall soon be advertised of its presence in the interior of the body, where it will defy the power of art.

There are still two remarkable circumstances which may serve to give us a knowledge of the organic alteration which constitutes erectile tumors, as well as its character. The first is the consistency of the tumor which it forms: it is granulated, soft, reducible on prolonged pressure—so much so, that we may thus reduce the affected part to a volume much less than that which is natural to it; we may even obtain this result in changing the attitude of the member on which it is placed. Thus, on the one side, the soft unequal consistency of the tumor, its susceptibility to be reduced by prolonged pressure or change of attitude, whatever may be its form and extent, are characteristics of this disease. On the other hand, when we can discover this characteristic softness, or produce a sudden lessening of the tumor, we may be assured that the organic alteration we have described (erectile tissue) exists. It is true that we may possibly find a difficulty, in spite of those data: we may get an erectile tumor with a central cellular cavity; in this case, compression will not force back the blood into the vessels; and this case is the more serious, as the pulsation which we can distinguish may give reason to suspect the presence of aneurism.

When the disease affects the extremities of long bones, it is almost impossible, in the earlier stages, to catch its characters so as to establish our diagnosis with the necessary exactitude.

There is one circumstance connected with the development of these tumors which I confess my inability to determine: I mean the power to state, upon looking at the tumor and the patient, whether it proceeds from a local irritation, confined to the given point, or whether there be a general disposition in the circulating system to the generation of this new tissue. When congenital, we cannot determine the question except we see them on various parts of the body; but when accidentally produced, if we cannot refer the disease to a local irritation (such as a puncture, contusion, or other irritant), we may fairly presume upon the existence of a general tendency in the system to produce this particular disease.

In either case our course is the same: remove the tumor by those means best adapted to the particular case.

These tumors are always of a serious character, and are the more especially so when they are accidentally produced. Although they may rest stationary, it is a dangerous doctrine to act upon. They may, however, remain so for a long time; yet, under new stimulations, or even without known cause, they may become irritable, accompanied by an itching, frequently compared by the patient to the presence of an insect in the part. The tumor then reddens, tumefies, and enlarges; the pellicle by which it is covered becomes thinned, is destroyed, and blood flows. At last, by repeated irritations, the hæmorrhages become more frequent, are less easily arrested, enfeeble the patient, and ultimately destroy life. It is, then, by loss of blood, by general debility constantly augmented, rather than by any disorganization of the affected part, that death is produced in persons suffering from erectile tumors.

In this disease some difficulty exists in determining upon the proper mode of treatment; for it is clearly established, upon the best possible evidence, that a simple erectile tumor, possessing no malignity, shall, under the influence of irritating applications, become the seat of a morbid deposition of a malignant character. Indeed, this disease may degenerate in a similar manner to a common in-

flammation, which will, under certain circumstances, assume a carcinomatous character. A common syphilitic ulcer upon the prepuce, shall, under the influence of irritating applications, terminate in a carcinomatous affection, which will necessitate amputation of the penis. An ulceration upon the lip shall, under similar circumstances, experience similar degeneration: a blow on the breast may occasion, in that organ, the development of carcinoma; a long-continued irritation of hæmorrhoids in the rectum shall occasion schirrhus.

In all these cases we may, by the early application of the knife, remove this disease; but if we neglect to remove it in its first appearance, the disease will be certainly fatal.

That peculiar character of the countenance which indicates a carcinomatous cachexia, is, I apprehend, in all cases, dependent upon the absorption of the carcinomatous matter which has been deposited in a particular organ; and when this absorption has been effected, the removal of the local disease will not save the patient, for it will be reproduced in different organs by a deposition from the blood.

So it is with those tumors produced by the development of erectile tissue, and which have undergone the degeneration I have now attempted to describe: if they be entirely removed, immediately this change is manifested, we may save the life of the patient; but if this precaution be neglected, and the absorption have been allowed to occur, the time for operation is passed; for even although we remove the limb upon which this disease is developed, we shall find in a very few days that the disease will be manifested upon the stump.

A gentleman had a simple erectile tumor on the tuberosity of the tibia, which was constantly irritated by his clothes; it increased in size, became ulcerated, and the seat of a constantly recurring and considerable hæmorrhage. The tumor was removed by the knife, and the wound had nearly cicatrized, when a fungous projection was discovered in one corner: it soon became as large as the former. Nitric acid and some other escharotics were applied to it, but its progress was not arrested. The leg was removed, and, as the stump began to cicatrize, a tumor was manifested there, from the effect of which the patient died. The tumor which was

removed in the first instance was very carefully examined, and contained *nothing* but a congeries of blood-vessels. The one which was examined upon the amputated limb, contained a large deposition of cerebriform matter; and so did the one which was developed upon the stump.

This case is not singular; I may refer to many others contained in books; but it is unnecessary. My object is merely to shew, that, to these tumors, irritating applications are not made without risk.

Whether the removal of these tumors be effected by astringent applications, by compression, by acupuncture, by vaccination, by seton, by ligature of the tumor or of the artery, by the actual or other cautery, or by the knife, provided the whole be removed, it will succeed. The cure of this disease can only be effected by the entire destruction of the diseased tissue. This, on paper, may appear a simple business, yet it is not so; great difficulty will be occasionally experienced in determining, with exactitude, its extent, and when this is ascertained it may be impossible to remove the whole.

The irritation which is excited by an operation, in any part of the tumor which may be permitted to remain, most frequently hastens the ulterior progress of the disease. Examples are not wanting, where repeated dissections and successive amputations have been rendered necessary, yet perfectly useless, in consequence either of negligence or the impossibility of knowing the exact extent of the disease; and it is upon this circumstance that is particularly dependent—the difficulties by which a prognosis of this disease is surrounded.

In the several modes of treatment which have been employed for the cure of this disease, our object is either to lessen materially the quantity of blood passing into the tumor,—in accordance with the principle that all those accidental productions are endowed with less vitality, or at least less tenacity, in retaining life, than is the case with the natural productions of the economy: whether this depends on a less perfect organization is not certain. This would appear to be the *modus operandi* of tonics or astringents, and ligatures placed upon arterial trunks at a distance from the disease, and perhaps occasionally with compression. To procure inflammation and obliteration of the vascular

net-work, which is the end proposed by acupuncture, vaccination, or seton. To destroy the continuity of the vascular communication, in isolating the tumor by means of a circular incision, including the whole of the tumor. To remove entirely the whole of the morbid tissue, either by the application of the actual or other cautery, by surrounding it with a ligature, or excising it with the knife.

For the purpose of curing this disease, which of these is the preferable agent? Each has succeeded—all have failed. The mode of treating these tumors by tonic or astringent applications, is seldom practised, and can scarcely ever succeed: applications of any kind are rarely made to them, unless they shew a disposition to increase. The application of astringents, supposing it can succeed at all, must necessarily require a considerable time for the accomplishment of this object; and during this time the tumor may acquire a rapid development, and we shall have lost time which may have been employed in removing the disease by other agents.

In the hands of Abernethy this method appears to have succeeded, in the removal of an erectile tumor existing in the orbit, but some months were required for the purpose; and this is one of the very few well-authenticated cases in which this method of treating the disease has succeeded.

The operation of placing a ligature around the arterial trunks by which the tumor is presumed to be supplied, is another uncertain mode of curing erectile tumors. The principle upon which we repose in the employment of this method of treatment, is, as I have already stated, to lessen the quantity of blood which is ordinarily carried to the tumor. Wherever the tumor be situated, and however near to the disease we can apply the ligature, we cannot entirely cut off the supply of blood; so complete is the anastomosis of vessels over the whole of the body.

Pelletan appears to have been the first who performed this operation: he tied the external carotid for a “fungous” disease, occupying the temple and the external ear, but without success. Indeed, when tumors of this kind affect the head, there is much difficulty in determining upon the best mode of treatment. When they affect the orbit, the ligature of the common carotid usually succeeds. Among other au-

thentic cases are those of Travers, Dalrymple, Roux, and Arendt.

When it is seated in, or posterior to, the temporal fossa, the same operation will not cure it. This phenomenon is well marked in the case of Roux. The tumor occupied the orbit and extended to the temporal fossa; he tied the common carotid: the disease of the orbit was cured, while that of the temporal fossa remained. He has also cured a similar tumor on the cheek and superior lip, by tying the labial and suborbital arteries. Lallemand has tied the crural artery with success, in a case where the tuberosity of the tibia was similarly affected.

Opposed to these cases are those performed by Mr. Wardrop, for a similar tumor on the cheek; by Dupuytren, for one on the ear, and another on the tibia; by Mr. Hodgson, for one on the thumb, in which he tied the radial and ulnar arteries; by Mr. Lawrence, in a case where the ring-finger was affected, in which he tied the radial and ulnar arteries.

It is worthy of remark, that the ligature of the carotid has never succeeded in any of the cases in which it was employed by Pelletan, by Mussey de Damsouth, and Wilhaume, for the cure of erectile tumors affecting the temporal fossa. We see, then, that in the employment of this operation there should be much reserve, for its successes and reverses appear rather equally balanced.

But if we separate the cases, and see the effect of the operation when applied to particular situations, we find that the ligature of the external carotid has succeeded in each of those cases where it was performed for the cure of erectile tumors occupying the orbit. We should therefore be justified, in this particular case, in performing this operation; while, on the contrary, when they occupy the temporal fossa, it has never succeeded: here, then, we are not justified in attempting this operation, but must resort to some other mode of treatment.

How can we explain this remarkable difference in the effect of a similar operation performed for the cure of a similar disease? Simply, I apprehend, for this reason—that the ingress of the blood into the tumor is more completely cut off in the one case than in the other.

That this is the case, appears to me probable from the case of Roux and from the case of Lawrence: in the latter, the ulnar and radial arteries were

tied without effect,—simply because they did not cut off the circulation sufficiently; for when he isolated the tumor by an ulterior operation, the disease was cured.

We may tie the radial and ulnar arteries for a wound of the palmar arch, and they shall not restrain the hæmorrhage; but if we then tie the humeral artery, we may effectually arrest it.

No one can be at a loss to explain this apparently singular circumstance. To every one the astonishing variety in the distribution of the arteries of a third or fourth rate calibre, is familiar: in one case we shall get the ulnar the larger, in another the radial, and in a third the interosseous. In the latter case (or, indeed, in either of the three cases), two of the arteries may be tied, and the third shall entirely and sufficiently supply the organ with blood.

With regard to the next mode of treating these tumors, compression, opinions are as various. It has frequently succeeded, among others, in the practice of Burns, Randolph, Roux, Abernethy, Sir A. Cooper, and Boyer.

Still, great as are these authorities, and much as I should defer to their opinions, I should strenuously insist upon the necessity, under ordinary circumstances, of abandoning the use of compression as it is usually made; for I agree entirely with Bateman, in the opinion that pressure made upon these tumors, supposing we have no point-d'appui, will have a tendency to cause an activity and a subcutaneous extension. Even when we have a resisting point, the same thing frequently has taken place.

Supposing compression to be preferred in the treatment of this disease, I would recommend that it be made by means of an instrument large enough fairly to surround the tumor, and hollowed in the centre, to admit it within the circle. In this way we should have no pressure on the diseased structure, to excite in it a fatal activity or to produce a circumferential extension of the disease, and we should cut off the vascular communication by which the existence of the tumor is preserved.

The principle upon which acupuncture and vaccination of these tumors acts, is one which I submit I sufficiently proved in my "Series of Experiments upon Puncturing Arteries:" it is to excite inflammation in the vascular plexus: this is immediately followed

a deposition of coagulable lymph, and obliteration of the canal.

If this be the *modus operandi* of this agent, one thing is certain: it is that much time must be spent in accomplishing a cure by this means, for we must cause the obliteration of the whole of the diseased vascular tissue before we cure the disease. A simple puncture of an artery will not, under ordinary circumstances, occasion in it the development of inflammation; it is necessary that the irritation occasioned by the introduction of the needle should be frequently repeated before we can calculate with any certainty on having produced the action we require to ensure success.

Cures have been effected by this means under the direction of Dr. Marshall Hall, by whom the operation was invented; but I cannot hide from myself one circumstance: it is, that we are occasioning an irritation which may do harm, and that we are perhaps permitting the tumor to enlarge, so as to throw some difficulty in the way of removing it by ligature or the knife; and, lastly, it can only be applied when the tumor is either cutaneous, or immediately subcutaneous. It has not, however, been tried in a sufficient number of instances to enable us to refer to the results of the treatment as evidence of its frequent applicability.

With respect to vaccination, which has been recommended by Dr. Cummin or Dr. Young, for some doubt exists as to priority of suggestion, the principle is to effect the obliteration of the vessels composing the diseased tissue by producing in the tissues adjacent to them a suppurative inflammation:—for this effect to be produced it is necessary that the tumor be not deep-seated, or no good effect can attend this mode of treatment, and if the child have been previously vaccinated, the chance of success by this method is lessened. When immediately subcutaneous, I think this mode quite as likely, under ordinary circumstances, to succeed as the method by acupuncture. My experience decidedly induces me to look with little confidence on each of these means. With respect to the seton, the principle is the same as in acupuncture:—it will seldom produce the effect we wish.

Destruction by the actual, or other cautery, provided no portion of the tumor were left, would succeed, but it

is a dangerous mode of treatment; the irritation which it invariably develops gives to the tumor an activity which may occasion a rapid development. The throwing off of the eschar is occasionally followed by a profuse hæmorrhage, which is not easily checked. There is, however, a much more serious apprehension, which should never be lost sight of: this irritation may, and evidence goes to shew that it has excited the generation of medullary fungus; and this appears to me a very sufficient reason why, while we have any other mode of treatment against which these objections do not obtain, we should abandon cauterization. The modes of cauterization which have usually been employed are, emplastic escharotics, by Callisen, Wardrop, &c.; nitric acid by Travers and others; nitrate of silver by Guthrie and others; the actual cautery by Maunoir, Larrey, &c. If either of these modes of destruction succeed, the sufferings which they occasion, and the ugly cicatrices by which they are followed, are quite sufficient to interdict their use except in extraordinary cases.

Three modes of treating this disease still remain to be described: insulation proposed, I believe, by Dr. Physick, and performed by making an incision around the tumor, so as to cut off the supply of blood, allowing the tumor to slough off; ligature of the tumor performed either by passing two or more needles under it, so that they shall intersect each other, and placing the ligature around it, under the needles, as proposed by Keate, and performed by Keate, Brodie, and Sir A. Cooper, and Lawrence, or by passing under it a needle armed with two threads, one of which encloses either hemisphere, as proposed by White, and performed by Lawrence, Guthrie, Lym, and Carlisle; and extirpation with the knife.

In certain situations, where we can with certainty insulate the tumor, insulation may succeed—on the cranium, for instance; but even here, if the tumor be attached to the pericranium, it may fail, for the supply of blood may be derived through the medium of the bone; the tumor must also be sufficiently circumscribed to make it certain that no portion of the tissue extends beyond our incision. This operation does not appear to merit adoption; it possesses no advantage over the ligature or extirpation, and it possesses the following dis-

advantages; the tumor must slough off; and this effect is more tardily produced than when it is strangulated by a ligature; and as compared with the knife, it has these drawbacks—it leaves a suppurating sore; whilst after extirpation with the knife, you may have union by the first intention.

With the remaining modes of operating, the argument is reduced into a narrow compass. With the ligature, you are not certain that you are removing the whole of the tumor, and you have a suppurating surface, followed, not infrequently, by an unsightly cicatrix. With the knife you may have a momentary hæmorrhage, and that is, I submit, the only source of apprehension; and as counterbalancing circumstances, you may frequently get union before sloughing has occurred in the operation by ligature. Another and a most important advantage attending the operation of extirpation by the knife, is the power it gives you of examining the tumor for the purpose of assuring yourself that you have not suffered any of the diseased tissue to remain.

The success of the ligature is entirely dependent upon the possibility of causing it to embrace a portion of the healthy tissue, or at the least, the whole of the morbid production, and this we can seldom be certain we have done;—we must not confide in the suppuration which follows being sufficient to remove any remaining portion of the erectile tissue.

Extirpation of the tumor has very generally succeeded when it has been seated on the head or face. Maunoir, Wardrop, and indeed the majority of surgeons, have witnessed the success of this operation in these regions: the only serious drawback is the hæmorrhage with which the operation is usually accompanied; but when we are prepared for this, it is in our power, to a certain extent, to guard against any fatal complication of this kind. It must be remembered, however, that in these cases the actual, or other cautery, will seldom succeed in arresting it; and if the vessels be too small, or too numerous to allow of our securing them with a ligature, graduated compression is our sheet-anchor. In the extremities the same success does not attend this operation, for ablation of accidental tumors affecting the members, has always failed; indeed, it is rarely that they do not soon

reappear, even although the operation may have been followed by a plentiful application of the actual or other cautery. Amputation of the member upon which the disease is situated, and at a sufficient distance from the disease, is here too frequently the only remedy: it has frequently succeeded when extirpation of the tumor has failed; but for such an apparently inconsiderable disease a patient will rarely listen to such a proposal.

How may this variation in the effects be accounted for? Simply, I believe, by a reference to the origin of the disease. When this disease affects the head or face, it is usually a congenital disease; and when congenital, whatever may be its seat, this disease is much less serious than when accidentally produced. This tissue, when accidentally developed, will frequently resist the employment of those means apparently the best adapted for its cure, and this is especially the case when it affects the extremities of the long bones; for although we may amputate the member upon which it is seated even four or five inches distant from the disease, the disease will frequently reappear upon the stump.

It is not, therefore, I apprehend, upon the seat of the disease so much as upon the accidental production, that danger appears to attend.

If, then, the tumor be merely a slight deformity, or only a little painful, and without any disposition to augment, I would say let it alone; if it occasion hæmorrhages which endanger the life of the patient, remove it though you have no hope of cure, for you may prolong the life of your patient. Again, I would say, when these tumors are small and circumscribed, their excision is easy without danger, and almost always successful; but when they are large or diffused, their extirpation is difficult and dangerous.

There are a certain number of these tumors which, when congenital, are not subject to increase; they present a species of fringed circle, presenting at the centre the natural colour of the skin; they not unfrequently disappear of themselves. Supposing, then, we have an accidental tumor affecting the trunk, and from constant hæmorrhage, having a tendency soon to compromise the life of the patient, we are no doubt justified in endeavouring to remove it; and after having done so as effectually as we can,

if we still believe the extirpation to be incomplete, what should be our next anxiety? I apprehend it should be to exercise every means in our power to preserve a suppuration over the whole surface for an indefinite time. The disease, I believe, never reappears at the same point until the process of cicatrization is progressing. May we not thus, by retarding indefinitely this process, retard as long the reappearance of the disease?

CASE OF TETANUS.

With Remarks on the Division of Nerves as a Method of Cure.

BY JOHN MURRAY, M.D.

Deputy Inspector-General of Hospitals.

To the Editor of the Medical Gazette.

Cape of Good Hope.

SIR,

On the 1st January, 1833, at noon, surgeon Bailey mentioned to me that Mr. Sommerville and he had a case of fracture of the leg, with great laceration of the integuments, which had become tetanic, and a consultation was immediately held between us upon it.

Nine days previously, the patient, a fine stout healthy Dutch boy, æt. 10, had fallen from a waggon, and entangled his right leg between the spokes of one of the wheels, by which the tibia and fibula were both broken about three inches above the ankle, and the integuments in front dreadfully lacerated, (part of which was now sloughing) and the tibia was laid bare to some extent above the site of the fracture, although the fracture itself was not actually a compound one.

Amputation had been proposed in the very first instance, but the boy's father objected to it. The fractured ends of the bones had been placed in apposition, and the limb laid on the side in the relaxed position, and the patient kept low and quiet. Inflammation had run high; yet, considering all circumstances, the leg seemed to be getting on as favourably as could be expected till the preceding day, (31st December, 1832) when it was observed, at dressing, to be unusually tender, tremulous, and inclined to start, which, however, was little noticed or attended to at the time; and it

was not till 4 o'clock A.M. of this day, that it was discovered, on his getting some water to drink, that he was affected with incipient tetanus, viz. with great difficulty in opening his jaws, and stiffness of his neck, which symptoms were attributed by his relatives to his having perhaps been exposed to a current of cold air during the night, or to his having been much disturbed by noise in the street, and in the adjoining house.

An opiate, containing forty drops of laudanum, had been given in the morning early, and repeated before I saw him; and a terebinthinate enema had been administered, but without any benefit. The bowels had been freely opened the preceding day; the pulse was hurried, (110) but not hard; thirst great; perspiration copious; intellect clear.

On examination of the leg, he complained of its being very tender and painful, chiefly about the knee; it started frequently, and this was attended with a simultaneous pain in the chest and neck, and spasmodic contraction of the muscles of the neck, so that his head was pulled backwards. The injury of the leg, however, was so extensive that we could not know what particular nerve or nerves might be under irritation.

In the ham we found the integuments also so much bruised, superficially lacerated, and tender, that we could not examine the parts freely; but the skin of the back part of the leg, over the gastrocnemii muscles, was sound, and not painful on pressure.

Our attention, therefore, was turned to consider the nerves of the lacerated integuments on the anterior part of the leg as the principal seat of irritation; in consequence of which we decided on dividing the nervus saphenus at the knee, which is the main branch supplying these parts, and this was done accordingly. This nerve seemed enlarged and red, and the patient experienced great pain while incising the parts about it; but, on its being divided, he said he was quite relieved from the pain he previously complained of in his chest and neck, and the starting of the limb ceased for a time. The trismus, however, remained the same as before. We then cauterized the lacerated parts with a strong solution of argentum nitratum; and as he said he felt sleepy, he was left with directions to be kept perfectly quiet; but at the end of an hour, it was found that he had got no sleep, and that

all the tetanic symptoms were as bad as before.

Amputation was again thought of, but rejected for the reasons that it was opposed by the father; that experience had proved it to be a remedy little to be depended upon; and that the patient's death would no doubt be attributed to it by the relatives, if it were performed without success.

The division of that bundle of nervous fibres in the ham, termed the popliteal nerve, was then seriously agitated; but as it was considered that this operation would interrupt nearly the whole supply of nervous influence to the leg, and thereby probably prevent the chance of the cure of it being effected, should the tetanus be arrested, we thought at the time (perhaps erroneously) that we were not sufficiently authorised to perform it; and it was, therefore, agreed to trust to the effect of the general remedies most usually recommended.

Two drops of croton oil were first given, with a view to clear the intestinal canal; opium and camphor were afterwards liberally administered, and two enemata were given at an interval of five hours, each containing ℥j. of tartrate of antimony in four ounces of water, but without producing the least remission of the symptoms.

2d January.—The disease having continued gradually to increase to complete opisthotonos, and seeing the melancholy agitated state of the shattered limb, our prognosis was now most unfavourable. The pulse had got up to 140, and was much increased in frequency during every access of spasm, but was not irregular. Now, at the same time that stimulating embrocations were applied to the spine, the effect of tobacco, in various ways, was tried for the greater part of this day, viz. by the mouth, by enema, and by cataplasm to the stomach and jaws, as well as to the wounds; but although very severe sickness, and great reduction in the strength of the pulse were produced, the tetanic symptoms were not at all mitigated; and I may mention that vomiting did not supervene, though the bowels were opened by it. He was afterwards ordered as much wine as he could drink, and opium was again used to mitigate his sufferings, but the disease was not to be arrested.

3d.—He lingered out this day in a most distressing state, being unable to swallow, receiving perhaps little benefit

from injections of broth, and apparently no ease from the opiate remedies that were continued to be administered, and he died in the evening about 9 o'clock.

4th, 8 A.M.—The father would only consent to a cursory examination of the limb, which was observed to have become livid. On dissecting the parts about the groin, the femoral glands were found much enlarged, and of a livid colour. The crural and saphena veins were of natural appearance; the femoral artery was of a darker colour than usual; the crural nerve was natural; the long cutaneous branch, or *nervus saphenus*, was red for about half an inch above where we divided it, and it was so also below the division; but most of its ramifications were soon lost in the lacerated integuments.

We then examined the state of the popliteal nerve. The integuments of the ham over it were lacerated and bruised, and its sheath, or proper membrane, was highly injected with blood, which might have arisen from the inflamed state of the integuments; yet, from this downwards, the nerve was remarkably red in all its ramifications in the direction of the fracture. Its external branch, however, which runs superficially on the gastrocnemius muscle, was of a natural white shining appearance. We considered some of the ramifications to be enlarged. The state of the fracture was found to be a comminuted one, and the muscular parts about it were quite black, from inflammation and from being injected with extravasated blood.

REFLECTIONS.—The primary injury of the limb was so great in this case, that, even if tetanus had not supervened, there was scarcely a chance of its being saved. The first proposal for its amputation, which was not acceded to by the father, would therefore have been the best mode of treatment; but a surgeon is obliged to yield, although his judgment tells him that there is danger in endeavouring to save a shattered limb, when the patient insists on his giving it a chance.

When tetanic symptoms arise from the irritation of wounded nerves, and the source of the irritation is very extensive and deep-seated, as doubtless was the case here, experience assures us that there is no probability of curing the disease by internal medicines or external applications; for it would appear,

that while the local cause exists and the irritated nerves remain undivided, the morbid influence continues to be propagated along them to the general nervous system, and keeps up the derangement of its functions; thus rendering the effect of such treatment entirely nugatory, and the result invariably fatal.

In regard to *amputation* as a remedy in such cases, we should, indeed, conceive that it might have a chance of success, if performed *instantly* on the first decided symptoms of tetanus appearing; but if a single day be allowed to pass over, nay, a few hours, then experience has fully shewn that it is generally of no avail—the nervous system, having already come under a state of great irritation, on its incurring such an additional shock from this severe operation, seems to have the morbid impressions aggravated thereby, and to be hurried into greater disease, rather than to be relieved and soothed; but, without attempting to account for the cause of its failure, it is enough to say that instances of recovery after amputation are so very rare, that its performance is not to be encouraged, and some other mode of treatment must be devised for success.

When the nerve under irritation can be distinguished with certainty, and when its *division* between the seat of injury and the sensorium can be safely effected, this operation certainly seems most worthy of trial, and ought to be put into execution without delay; and I must confess, that after seeing the state of the parts in the forementioned patient, I regretted exceedingly that we had not divided the popliteal nerves within an hour after the first operation. I am now convinced that our reason for not doing so was not a valid one; its worst effect would probably have only been a temporary paralysis of the leg, and even if it had caused permanent paralysis, or the loss of the limb, provided it had cured the tetanus and saved the life of the boy, it would have been valuable; and had it been performed here, it would have put the value of the remedy fully to the test at all events, and thereby afforded important information in regard to what dependence is to be placed on it. I consider, therefore, that we are rather to blame for not having performed it; at any rate, I should not hesitate, *in such another desperate case*, to divide the whole nerve of a limb, rather than

allow the patient to die without giving this operation a fair trial; for, as far as I know at present, I think it was the most likely, if not the only remedial, means which afforded him a chance of recovery.

I am still, then, in the hope that a light has been thrown upon the pathology and treatment of this hitherto most fatal disease, by my nephew's successful case in the "*Pattison*," in which he divided the nerve supplying the injured parts with such apparently instantaneous benefit; and although the present was one of a complicated and untoward nature, in which it became a delicate question to follow up his idea to the full extent, and to decide upon and execute the cutting off the whole nervous communication between the injured limb and sensorium, as in his clear case, yet, as I have said before, I now think this might have been done here, and be safely carried to the fullest extent in desperate cases, as we are then warranted to employ the most powerful remedies if they hold out any hope whatever of success; and, in such hopeless diseases, the old maxim, "*melius anceps remedium quam nullum*," certainly urges us to try something new in the bad cases of traumatic tetanus, as it is but too well known that none of the medicines and plans hitherto devised for its cure deserve to be considered of much value; on the contrary, I believe that patients often die sooner from their influence than if they were entirely left to nature.

As to the pathology of tetanus, it seems generally agreed that the disease consists essentially in a derangement of the functions of the nervous system; but it is extraordinary that we should still be in doubt whether the spasmodic muscular actions arise from a state of increased or of diminished nervous energy—*i. e.* whether the nervous influence be unduly excited or unduly depressed; and hence it is that there is so much vacillancy in the mode of practice, and that remedial means of a diametrically opposite nature continue to be tried (as if experimentally) for its cure. This is an important question for physiologists to solve.

ON THE UTILITY OF ARSENIC IN CHOROIDITIS.

BY WILLIAM MACKENZIE,

Lecturer on the Eye in the University of Glasgow.

THE disease to which I have given the name of *Choroiditis*, but which perhaps might be more properly called *Sclerotic-choroiditis*, may readily be distinguished by the following symptoms:—

1. Varicose dilatation of one or more of the arteries derived from the recti muscles*, the enlarged artery or arteries ending in a broad lash of small vessels near the edge of the cornea. It may be the arteries from the upper, lower, outer, or inner side of the eye, which are thus affected. The upper and outer sides, however, are more liable than the inner or lower.

Fig. 1.—First or inflammatory stage of choroiditis.

2. Under these vessels, the sclerotic has at first the appearance of being thickened, but after a time is evidently thinned, so as to allow the dark choroid to shine through it, of a livid colour.

3. By and by a protrusion, or several separate protrusions of the choroid, take place, through the extenuated sclerotic; a symptom to which the term *sclerotic staphyloma* has been applied.

Fig. 2.—Second or staphylomatous stage of choroiditis.

4. Dislocation of the pupil; this aper-

* These arteries are seven in number; two proceeding from the rectus superior, two from the inferior, two from the internus, and one from the externus.

ture moving towards the affected portion of the choroid, in some cases so much as to be placed behind the edge of the cornea. This symptom is not constant.

5. Specks of the cornea, especially towards the edge next the affected part of the sclerotic and choroid. (See Figs. 1 and 2.)

6. If completely uncontrolled, the disease ends in general enlargement and protrusion of the eye, the cornea becoming totally opaque, the whole sclerotic thinned, and the choroid exposed; so that the eye is of a deep blue colour, with varicose vessels streaming over it.

After trying in this ophthalmia many remedies, most of which failed in producing any effect, I have found one which has proved decidedly useful. I am anxious that other practitioners should try it. It is the arseniate of potass. I began to use this medicine in cases of choroiditis, at the Glasgow Eye Infirmary, in April 1830, and under its influence upon this disease, I have had the satisfaction, in a number of instances, to observe the varicose vessels to shrink, the blueness to become whiter, the humour of the sclerotic and choroid to fall, and the patient's health and vision to improve. The dose with which I have generally commenced is the thirty-second part of a grain, thrice a day, in the form of pill. Of course, no one will expect a large *sclerotic staphyloma* to disappear under any treatment: nor must it be supposed that I propose arsenic as a specific for choroiditis, any more than, in 1828, I proposed the sulphate of quina as a specific for the scrofulous ophthalmia. Attention to the general health, and also to the local symptoms, must not be neglected, although the patient is put upon a course of arsenic.

It was not till I had succeeded in subduing several cases of long-continued choroiditis by means of this medicine, that I was struck with the probability, resulting from the analogy which certainly may be traced in some respects between the rete mucosum and the choroid, that the diseases of the one of those textures might be under the influence of the same remedies as those of the other. Now that I am fully convinced that inflammation of the choroid, one of the least tractable ophthalmia, is greatly benefitted by the same medicine which exercises so powerful an influence over some of the most

tedious cutaneous diseases, I am still more led to reflect on such facts as the congenital deficiency of colouring matter in the skin and in the choroid which occurs in the albino, and to suspect that other points of resemblance may probably exist which have hitherto escaped observation.

MEDICAL STATISTICS.

PROPOSED REGISTRY OF THE CAUSES OF DEATH.

To the Editor of the Medical Gazette.

SIR,

YOUR readers are probably aware that Mr. Wilks has recently, with the consent of all parties in the House of Commons, obtained leave to bring in a bill for better regulating the registries of births, marriages, and deaths, throughout England. From this measure much curious and instructive information may reasonably be anticipated in the department of medical statistics. To obtain the greatest quantum of benefit from this proposed bill, is surely desirable; and it is on that account I venture to address you. My object is, to impress upon the legislature the propriety of including in this bill the mechanism necessary for registering the *causes of death*; in other words, of extending throughout England, and giving a legislative sanction to, the system now pursued in the London bills of mortality.

To shew the reasonableness and probable advantages of such a design, may be considered perhaps superfluous; nevertheless, I cannot avoid mentioning a few facts, by way of illustration. In the extensive parish in which I reside (Marylebone), not included in the bills of mortality, there are no searchers, nor any means of ascertaining the diseases of which the parishioners die, other than is afforded by casual conversation at the burying-ground. The number of deaths from the 1st January, 1833, to the present day, exceeds by 60 the corresponding period of last year, when cholera was among us! The diseases which appear *now* to be in the ascendant, are, inflammation of the lungs, small-pox, measles, and hooping-cough; but the

parochial authorities, with the most praiseworthy readiness and even *anxiety* to forward my views, are unable to give any details as to the comparative mortality, at the present time, of those four disorders. This surely needs correction, more especially when the means of correction are neither difficult in design nor in execution.

I am, sir,
Your obedient servant,
GEORGE GREGORY.

31, Weymouth-street,
March 30, 1833.

SINGULAR RECOVERY FROM ACUTE RHEUMATISM.

To the Editor of the Medical Gazette.

April 1, 1833.

SIR,

IN the space of a few months a family consisting of four daughters, have each successively been attacked with small-pox, measles, and scarlet fever, two of them subsequently suffering from acute rheumatism. It is not this rapid succession of disease, strange as it may appear, that has led to this communication; the singular, I may say the extraordinary, termination of one of the cases, induces me to record it.

The eldest daughter, after recovering from a very severe attack of scarlet fever, exposed herself to the prevailing weather of last month. An attack of rheumatism was the consequence. During four days the general excitement, and the local affections, were far from moderate; on the fifth morning (about ten o'clock) I found her in the *deepest sleep*, into which state she had suddenly fallen while drinking some tea about eight o'clock. I learnt that the night had been passed in every discomfort, and that she had gradually become perfectly deaf.

It was with great difficulty I awoke her; but on doing so there was perfect consciousness. In a second the sleep again overpowered her, and in this state she remained until half-past five in the afternoon, when she awoke, hearing distinctly, and the rheumatic affection gone. She has rapidly recovered.

That this sudden cessation of disease was the effect of one of those efforts of

the constitution which occasionally awake our surprise, and utterly mock our powers of imitation, I can scarcely for a moment question.

I am, sir,
Your obedient servant,
HENRY GEORGE.

Philimore Place, Kensington.

" LONDON UNIVERSITY."

To the Editor of the Medical Gazette.

SIR,

THE establishment of the London University originated in a principle which appears to me to be founded on reason and common sense. Many persons of property and respectability, amounting to a very large proportion of the population of the country, object to subscription to the thirty-nine articles, and they see no reason why a person should be prevented from taking a degree in laws, arts, or medicine, without being required to sign a test of their religious creed. They probably would not object, either for their children or themselves, to attend prayers morning and evening, according to the liturgy of the church of England, if that were all; but that they should be compelled to subscribe to articles of belief which involve a great many points, as to the interpretation of which churchmen themselves are not agreed, is as repugnant to their principles as it is opposed to sound sense and reason: and yet this has been made the bar to admission to the highest honours of the profession, and the College of Physicians refuse (*it is said* in the very face of the statute) to admit as Fellows any one who has not graduated at Oxford and Cambridge.

When the chairs of medicine and philosophy, at Edinburgh, were filled by Black, Cullen, and Gregory, Playfair, Leslie, and Dugald Stewart, its school was justly considered the first in Europe, and thousands flocked to its walls to be educated in the science of medicine; but of Edinburgh now, it may be said that its lustre is tarnished and its splendour beclouded. Although, however, the London schools of medicine are now superior, both in theory

and practice, and in the opportunities they afford for the acquisition of knowledge, a young man must go to Scotland for a medical diploma, notwithstanding that the sources of information are as pure, as abundant, and as scientific, many hundred miles nearer home. I have a relative whose father objects to subscribe, and he himself professes the same opinions. He has studied for two years at Cambridge, but this is of no avail in bringing him any nearer the degree of M.B.; he must now study for four years at Edinburgh, and then will be obliged to come to London to see hospital practice. To be sure it may be more prudent, perhaps, to subscribe first and see the objection to the articles afterwards,—as is done by your talented contributor Maxilla; but I leave it to others to decide which is the more honest—he who sacrifices future prospects on account of his principles, or he who first attains all he wants by compromising his principles, and then begins to feel and express strongly enough the force of the objections.

These were the evils which pressed, and still press, upon those who were the founders of the London University. The King's College followed in its wake, but its establishment was based on a very unworthy and illiberal jealousy. "Religious instruction" was the cant term employed to excite contributions, although every one who inquires into the merits of the two institutions will find, that, as to real religion, there is quite as much at one institution as the other: and, indeed, we may go farther, and assert, that in the Universities of Oxford and Cambridge, no one will accuse their alumni of being righteous overmuch; a love of dash, and taste for dissipation, are much more general acquirements: so that, *ceteris paribus*, an impartial person would be inclined to decide rather in favour of the religion and morals of the young man educated at Edinburgh than of the one educated at the English Universities.

If, then, as to religion, morals, scientific education, and practical experience, the balance is by no means decidedly against, but rather in favour of, an extra-collegiate education, the founders of the London University were right in endeavouring to establish a school of general science near their own doors.

The course that has been taken by

the Medical Gazette has disappointed many of its friends and readers;—always “damning with faint praise,” it now openly exults in its disasters; and it has adopted the tone and spirit of the partizan rather than the impartiality of the candid journalist.

The London University was not established as a medical school only, or principally. Its medical classes have far outstripped the literary ones certainly; but this was by no means anticipated, or calculated on, or they would have been more careful to have provided the school with an hospital. The superiority of the medical school has arisen from the excellence of the teachers, from the pains taken with the pupils, the frequency of examinations, the extent and copiousness of the several courses, and by the public exhibition of premiums and prizes; and the stimulus, and emulation, which have been excited in the other medical schools, are productive of no ordinary benefit. Nor is the obtaining a charter a circumstance so improbable as it is attempted to shew. The fact is that the charter has actually long since received the royal sign manual; and if it had arrived from Brighton on a sealing day, the charter would be at this moment in operation; unfortunately, however, a day intervened, and on that day a letter was received from the Chancellor of the University of Oxford, stating that it was intended to oppose the charter. Whether or no it be destined to receive the seal at some future period, time will shew. The friends of the London University need not despair even yet of its becoming, at no distant time, a school of general literature and science. We would exhort them, in spite of the contemptuous sneers with which they are assailed, still to persevere in that object. From the other medical schools they must, of course, expect opposition and rivalry; but if they zealously persevere, they will doubtless ultimately be successful.

I am, sir,
Your obedient servant,
C * *.

P.S.—It is fair to add that I am neither directly nor indirectly connected with any of the institutions to which I have alluded, and that I am not personally one of those who object to the test required by the universities.

[We have left out a paragraph at the beginning of the preceding letter, which we considered uncourteous, and which, if we chose to be punctilious, might have warranted us in excluding the whole; the writer, besides, has not favoured us with his name; but as we have, in other respects, no possible objection to the publication of the letter, we will not stand upon ceremony.

Our correspondent does not do us justice, if he means to aim a shaft at us, in noticing the “principle” upon which the “University” was founded; for we never either advocated subscription to the “articles,” nor have we ever once meddled with the religion or irreligion of the place which he upholds. And it further seems to us perfectly idle in our correspondent to introduce mention of *the* Universities and the College of Physicians—as if what was objectionable in them, or in need of reform, afforded the least ground for establishing a “University” in Gower-street. Surely it does not follow that, because articles must either be subscribed in this country, or a degree travelled for to Scotland, a joint-stock company should be all of a sudden empowered to grant degrees, or to assume the title of University; (an assumption which we always ridiculed*) and if this held good at its outset, how much more strongly does it hold now after we have seen how the machinery has worked?

The reflection on King’s College is too ill-natured to be worthy of notice—indeed, attributing unworthy motives to others seems to be the besetting sin of our correspondent; and we must add that we do not exactly see the force of the allusion to the “real religion” which is to be found, or not to be found, (we do not know which) in Gower-street.

As to our “damning with faint praise” any set of men or measures, those who know any thing of the Gazette are aware that such a practice is none of ours. No; we never scruple to “damn” with the most downright open censure whatever we deem worthy of condemnation; and when the “University,” or any other place, renders itself offensive by the most unwarrantable puffing and humbug—professing to do what it cannot, and knows it cannot, do—and systematically and openly pretending to privileges which it does not enjoy, and excellencies which it does not possess—we shall never flinch from the duty we

* See vol. ii. page 602, and subsequent vols. *passim*.

owe the public to expose such impudent assumption. It is rather too late for our correspondent to talk of the "superiority" of the Gower-street school, as to the fulness, &c. of the courses there: where was he a few months back when we adjusted this claim, in the teeth of the professor of medicine, by proving even to demonstration that the pupils of the "University," so far from enjoying advantages over those in all other schools, possess even less than those in some, in point of the "extent and copiousness of the several courses," and other sources of medical education.

With regard to "exulting" in the said University's "disasters"—we thank our correspondent for the word—not "exulting," for that we have never done—we have merely told the truth; but because he has the candour to admit what we alone, upon the showing of the Council, and in despite of interested counter-statements, thought it right to lay before the public, namely, that the place is, and has been, labouring under "disasters." The charter anecdote is *good*, but rather overdone; and as for the conclusion of the letter, it being matter of taste, and no doubt kindly meant, we shall not interfere with it: neither shall we meddle with the postscript, for it is of not the least consequence with reference to the argument—whether Mr. C*x is a proprietor or not.—ED. GAZ.]

MEDICAL GAZETTE.

Saturday, April 6, 1833.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

NORWICH JURY OF MATRONS.

A TRIAL, of more than usual interest, and involving some medico-legal considerations, has recently taken place at Norwich. We shall first relate the leading particulars, and then offer a few remarks.

Mary Wright, aged 28, was indicted for the murder of her husband by poisoning him with arsenic. The symptoms of the deceased were mistaken by the

attending surgeon for those of cholera; but suspicion having been awakened after death, the body was disinterred, and the stomach examined. Mr. Crosse, the surgeon of the Norwich hospital, undertook the pathological examination of the tissues, while the contents were submitted to the analysis of Mr. Bell, the chemist. From the evidence of Mr. Crosse, it appears that the stomach presented increased vascularity, inflammation of the lining coats, principally in the cardiac portion and the greater curvature; that the appearances, in short, might have been produced by arsenic, but certainly that the contents were not such as would be found in a man who died of cholera. Mr. Bell tried the usual liquid tests, and found that the presence of arsenic was indicated by them all, but he did not reduce the metal. "I used," he said, "every test that I could recollect, but I had not a sufficient quantity to produce arsenic." The circumstantial evidence respecting the buying of arsenic by the prisoner, and the purchase of currants for the cake in which the poison was alleged to have been exhibited, and the discovery of currants among the contents of the stomach, made the case for the prosecution as strong as it could well be. On behalf of the prisoner, an attempt was made to prove her insanity; but though it was put beyond a doubt that she had been occasionally insane after her last confinement, and that insanity was in her family, yet the proof failed in establishing her mental alienation about the time that the criminal act was committed. The jury, after a short consultation, returned a verdict of guilty, and sentence of death was passed, to be put in execution on the following Monday. The trial took place on Friday. But now comes the circumstance which we deem most remarkable in this trial. The prisoner's counsel put in a plea of pregnancy in bar of execution, and the judge (Mr. Baron Bolland) immediately directed the sheriff to summon a jury of

matrons to inquire into the truth of the plea. Twelve married women were accordingly sworn to try whether the woman was pregnant with a *quick* child. The female jury and the prisoner retired into a private chamber; and in the course of an hour returned into court, and gave their verdict that the prisoner, Mary Wright, was *not quick with child*. Fortunately, the eyes of the profession in Norwich were not closed to the absurd nature of this transaction: three gentlemen, with the humanity which is seldom absent from minds of superior attainments, procured access to the prisoner next morning, examined her professionally, found her to be pregnant with a quick child, drew up a representation instantly for the judge, to the facts of which they were obliged to swear; and the consequence is that the woman stands reprieved from the execution of her sentence.

Now it may be said that it remains for time alone to determine whose verdict is the true one—that of the *matrons* who were casually and unexpectedly called upon for an opinion—or of the professional inquirers who so promptly took the matter up, and came to a conclusion for the correctness of which their reputation, in some degree, stands pledged. There is some truth in this, no doubt; but, under the circumstances, we are far from being convinced that it is at all unwarrantable to forestall the event: the probabilities are so clearly all one way, that we feel ourselves as justified in making the following observations as if the prisoner were already delivered of a quick child.

Admitting, for a moment, the competence of a matron jury to decide a question on which the life or death of a convicted criminal depends, we must take leave to offer our primary protest against a power so serious being entrusted to such female stragglers and idlers as chance finds present in a criminal court on such

an occasion. Such persons must be, literally, loungers and idlers; for it is to be presumed that the jury is not formed of the female witnesses for the prosecution and the defence—the only females who have business in court; and are these the “matrons or discreet women” whom the law, imperfect as it is, requires for such a purpose? If it be said that the woman jury must be got up *de circumstantibus*—we are even still more at a loss—for however possible it might have been in the olden time, and we greatly doubt the fact, that “matrons or discreet women” should form a part of the “common bystanders” at a trial for murder in low life, it must be allowed that times and manners have greatly changed, and that the forms which prevail in society at the present day render the very wording of the law, as it stands, a dead letter.

But we do by no means admit, even supposing that discreet matrons could be selected from the rabble crowd of a criminal court of justice, that such a tribunal is competent to decide any such question. We all know the extraordinary mistakes which even the majority of really discreet matrons will occasionally make concerning their own condition; and when we come to consider that the question of pregnancy, or no pregnancy, is often one of the most difficult that can be submitted to the accomplished accoucheur, few, we think, will differ from us in opinion, that it is not exactly a question on which mere matrons, or women however discreet, much less those picked from a vulgar crowd, are fit to determine. And if this be true of the simple question of pregnancy, how much more strongly should the objection hold when the vitality of the fœtus is concerned?

The jury was to try, we are told, whether the prisoner was pregnant of a *quick* child or not. We have looked carefully into several reports of this

trial which have been sent us, and we nowhere find that the judge, or any other officer of the court, gave the women any charge or instruction beyond the dry verbal announcement of their duty. Now we will venture to say, that of the twelve women who formed the jury, however they contrived to be unanimous in their verdict, no two of them, perhaps, were they separately examined, would be found to agree in the meaning of the term *quick*. It is a word which has undergone much mutation since it was once current in the legal sense. No doubt these women of experience know well enough the particular phenomenon in gestation which is designated by the name of *quickening*; but we must be excused for doubting whether that very name, with the meaning which they attach to it, may not have misled and confounded them in coming to a verdict relative to a *quick child*. What the woman jury in the present case was about, or what they did with the prisoner during the good hour that they were shut up together—far be it from us to be so bold as to inquire; we might, perhaps, as safely venture to pry into the mysteries of the *Bona Dea*: but they will pardon us if we surmise that—supposing they did more than *talk* the matter over—they were principally engaged in exploring whether there was *motion* in the fruit of the prisoner's womb. It does not appear that they called for any medical counsel: it is certain they received none: and behold the notable conclusion they have arrived at—"a *quick* lie," as the grave-digger in Hamlet says!

We know that those ancient sages who bestowed the name of *quickening* on that well-known change of position, or whatever it be, which is still commonly characterized by it, did so in their simple ignorance, on the supposition that not till then did the fetus become *quick*: and the latter term having

become obsolete in its original sense, and being now almost solely appropriated to speed and rapidity of motion, we believe that by "*quickening*" at present, the generality of women (among others the discreet jury) merely mean that the child has now acquired the power of sensible motion. If we be right in believing so, our inference is correct, that the said jury spent an hour in endeavouring to ascertain whether the prisoner's child could move or not; and as we presume they failed in assuring themselves of this, they left her and her offspring to die!

Such a jury as this, unenumbered with physiological distinctions, or etymological niceties, may be always expected to hand over to the executioner all undelivered babes of female felons, which have not attained the fourth or fifth month of their intra-uterine existence—and those even older, as in the case in question, if they have not given token of the movement that is in them. So much for this merciful provision of our ancestors, instituted *in favorem proles*!

Nor let it be supposed that the jury of matrons has acted otherwise than the founders of that institution originally intended. It is true that this sort of tribunal has been seldom called upon of late to exercise its peculiar functions, especially in cases of life and death; its revival now will, we hope, be attended with salutary consequences; it will give rise to an inquiry into the principles on which it is based—and the physiology which guided the legislators of our criminal code may now be fairly canvassed. The fact is, that there is a most remarkable anomaly in the practical doctrines handed down to us by our wise predecessors touching this matter of quickening; and whoever undertakes to defend them will find himself rather in an awkward dilemma. The punishment for criminal abortion is, or was till very lately, essentially dif-

ferent, according as the crime was effected before or after quickening—clearly showing that the authorities who framed the statute held at naught the life of the fœtus before quickening, while they extended to it their protection after that change had taken place. It is evidently on the same principle that a woman's plea in bar of execution is invalid during the first months of her pregnancy, her fœtus showing no perceptible signs of life during that time—or, in other words, not being considered quick. From the charge of this gross error our ancient codifiers can only be acquitted at the expense of their humanity: say that they considered the fœtus in utero alive from the moment of conception, how can they reconcile the fact of protecting it during one portion of its intra-uterine sojourn, while at another they allow it to be put to death along with the mother?

Granted then, as grant we must, that the old physiology of our lawgivers held the superaddition of the vital principle to the fœtus to take place at a distinct period of pregnancy, we have still another point on which we would fain have an explanation. Can there be any rational solution given why, if the fœtus be held unendowed with life until quickening has occurred, that very same fœtus is yet held capable of inheritance from the moment of its conception? In other words, an embryo, by the laws of real property, may succeed to an estate, and yet, in three or four months after, be put to death for its mother's crime!

Absurdities such as these are not the least among the inducements which should bring about a reform in several parts of our statute books. Habit and ancient custom reconcile the mere practitioner to endure their continuance unaltered: but the philosophic mind cannot contemplate them without pain; they are blots upon our legal system,

in their simplest aspect—they are snares for the entrapping of innocent blood, as they were about to prove in the case which has led us into these remarks. It is startling to reflect how many cases of this sort must have occurred at ruder periods, when there arose no safety, no help, for the innocent victim. From the very fact of the routinemanner in which the judge at Norwich proceeded in the track marked out for him by precedent—without turning to the right hand nor to the left—apparently never once dreaming that there was any thing absurd or wrong in what he was doing—it may at once be perceived how seductive is mere precedent, and how utterly unlikely to admit of change, even in matters affecting life and death, without the persevering and well-directed efforts of the real lovers of their species.

We will only add, that there are cases in which the jury of matrons has been dispensed with, in favour of a professional jury consisting of two surgeons and two physicians: let us hope that the discretionary power of such a dispensation may always be exercised by the bench in future, and that a select body like that of the discreet women who formed the jury at Norwich may never again have the chance of doing actual mischief.

We subjoin the document which procured the reprieve.

“Norwich County Gaol, Saturday, quarter before 9 A.M. March 23, 1833.

“*To the Hon. Sir Wm. Bolland, Knt. Baron of the Exchequer, &c. the following representation respectfully sheweth:*

“That we, the undersigned, are surgeons and accoucheurs of considerable experience in the practice of midwifery, and have repeatedly examined females in different stages of pregnancy.

That we have this morning strictly examined Mary Wright, a prisoner, sentenced to be executed on Monday next, for the murder of her husband,

and found her between five and six months gone in pregnancy.

"That, in an apparently vigorous and healthy woman like the prisoner, and where the size of the body has regularly increased during pregnancy, we should feel ourselves bound to believe the *fœtus* living, unless we found some signs of its being dead.

"That in the prisoner, Mary Wright, we find no signs of a dead *fœtus*; but, on the contrary, have positive evidence of its being at this time living.

"That we do verily believe the said prisoner is above five months advanced in pregnancy, and carries in utero a living *fœtus*.

"That, in a case of such a nature, we desire, without delay, to submit our statements to your Lordship; and if the verdict of the jury of matrons, yesterday given, *that the prisoner, Mary Wright, was "not quick with child,"* deprive the said prisoner of a reprieve until delivery *ex necessitate legis*, we humbly entreat your Lordship to respite the execution of the said Mary Wright until she be delivered.

(Signed) "P. N. SCOTT,
Surgeon to the County Gaol.

"J. G. CROSSE,
Surgeon to the Norfolk and
Norwich Hospital.

"J. G. JOHNSON,
Assist. Surg. to the Norfolk
and Norwich Hospital."

It is creditable to his Lordship that he acted promptly on this document, and, the facts and opinions which it contains having been sworn to, reprieved the prisoner till after her delivery.

COLLEGE OF SURGEONS—LOST DIPLOMAS.

A LETTER appeared in the *Times*, a few days ago, from Mr. Eeles, a member of the College of Surgeons, complaining that Mr. Myers, a friend of his, had lost his diploma in consequence of the house in which he lived being burnt; that on applying to the Court of Examiners, he was refused a new diploma, and only received a certificate of his having had one on the payment of five guineas. The story shews

primâ facie against the Court; for the case appears a hard one, the refusal unjust, and the price demanded exorbitant: we say *appears*, for there is something to be said on the other side of the question. Formerly, if a man lost his diploma, he could procure another; now he cannot, nor can he even obtain a certificate without some difficulty—and the reason is this. It was found that in numerous instances the possessor of the diploma sold it either to a person of the same name, (one flagrant example of which occurred in the sister kingdom) or the name was effaced, and that of the purchaser substituted. Meantime, the original party wrote to the College that he had irrecoverably lost his diploma, upon which he was furnished with another. The trick having been in some cases discovered, it was enacted that on no pretence should a second diploma be given to the same individual, but only a "certificate" that he was a member. Even this, however, was not an effectual prevention, for it was then found that some parted with their diploma, and practiced on the faith of the said certificate—its representative. It was now thought that by diminishing the profits of this swindling speculation, the evil would be abated; and with this view, a penalty of five guineas was attached to the procuring of a certificate. This expedient having answered the purpose pretty effectually, it became incorporated in the bye-laws sanctioned by the judges; so that the Court of Examiners cannot, if they would, make good the loss of a diploma except under the legal conditions. Whether it was judicious in those who framed the law to tie up their own hands, and those of their successors, (the present Court) may be matter of question, and we have no hesitation in stating our opinion that it was not so. There ought to have been some discretionary power; and as it is, it had been better to have returned Mr. Myers his money, after having gone through the ceremony of receiving it, rather than have given a handle to this charge of extortion. In a large body, where some unworthy members will unavoidably gain admission, some check to guard the public against the sale of diplomas is obviously necessary, and no one ought, as a matter of course, to expect a duplicate of his testimonial—a circumstance, by the way, of which every one is made

aware, and in which he acquiesces when he signs the bye-laws.

There is one point more to which we would advert: we have stated the facts because we happened to be aware of them; but this is not enough—the College ought to have done so themselves. When they are attacked by “A Student in Surgery,” and other anonymous writers, who adduce charges which are obviously frivolous and unfounded, it is not to be expected that the College should answer them; but when a gentleman brings forward a specific accusation, and guarantees its accuracy by attaching his name to it—and when a paper of such influence as the *Times* deems it worthy of an editorial notice—the Council owe it to the public and themselves to offer an explanation. Where, under such circumstances, it is withheld, they may rest assured the inference will always be against them.

VACCINATION.

At the meeting of the Académie de Médecine, Paris, of the 26th ultimo, M. Gerardin read a report on the state of vaccination in France; by which it appeared, that, since 1827, the number of persons vaccinated *had diminished very nearly one-half!* This fact is deserving the attention of the Committee in our own country, now occupied in investigating the vaccine question.

It appears that, from the time the functions of the Vaccine Board of France, and the maintenance of vaccination were entrusted to the Academy of Medicine, aided by a few prizes distributed annually by the government to the most zealous inoculators, the number of persons subjected to the protecting influence of the cow-pox has progressively diminished. The event alluded to took place nine years ago; and the apprehension of the consequences has recently become so great, that, in a paper of the 28th ult. which now lies before us, the press is urged to co-operate with the Academy in procuring the intervention of “authority.” In 1827, the number vaccinated in France was 404,495; in 1831, it amounted only to 214,360!

FACTORY BILL.

LORD ASHLEY’S bill, of which we gave an abstract the week before last, we are sorry to say, is, we fear, lost for the present. A commission has been appointed to collect more evidence! To those who have seen the mass of evidence already procured, this will perhaps appear incredible; yet such is the fact!

COLLEGE OF PHYSICIANS.

Monday, 25th March.

SIR HENRY HALFORD, PRESIDENT, IN THE CHAIR.

THE Registrar read a short paper from the pen of Dr. David Badham, “on the anticipation of modern discoveries in medicine in the works of ancient authors.”

The author, after some general remarks on the gratification to be derived from perusing the ancient masters of our art, observed that the classical student will oftener meet with what may be called “happy coincidences of expression than direct anticipations of what came afterwards to be known.” Dr. Badham drew his illustrations from the writings of Aretæus, and gave instances of his allusion to many pathological points, some of them not long familiar to modern science—as putrid sore throat, croup, &c. Some of the observations on insanity were likewise curious and interesting; among which we may mention his distinction between delirium and mania. “The delirious man (says he) sees things that others see not; the maniac sees no more than others see, but forms false judgment of things seen.” Another curious circumstance pointed out by the author of the paper, was the description of the anatomy of the liver given by Aretæus, which seems to be extremely accurate. To an inflammatory condition of the vena cava, the learned Cappadoecian attributed the fever he called *causos*; and this theory Dr. Badham contrasted with the views of some of the modern French pathologists on the same subject.

The meeting was thinly attended.

MEDICO-CHIRURGICAL SOCIETY.

March 12, 1833.

THE chair was taken by Dr. Elliotson, who (his name standing next on the list of physicians not practising midwifery)

had been appointed President, according to the established usage of following the order of rotation. The names of the other officers for the year were read over. The Secretary then read a paper, entitled "*Case of Œsophagotomy, with Remarks,*" by Mr. Arnott.

The main facts of this case are already known to our readers from our account of a former meeting of the Society, when Mr. Arnott related it, and from our report of a clinical lecture by Sir Charles Bell on the same case.

In the remarks, it was observed that systematic writers on surgery required, as circumstances justifying the operation, that the foreign body should impede deglutition, should threaten suffocation, and should project externally. Neither of these circumstances here occurred, and yet the operation was necessary, from the dread of ulceration of the trachea or the carotid artery, which was known to have taken place in other instances. Examination of the body proved that another danger is, in such cases, to be apprehended—chronic inflammation of the lung; of which the patient in question died.

With respect to the operation itself, Mr. Arnott thinks its difficulties and danger have been much exaggerated. It might not be easy to open the Œsophagus when flaccid, but this difficulty is obviated by the introduction of a catheter, and elevating the canal upon its point through the external wound. The most usual place for opening the tube will be at its commencement. In this case the incision into it was one-half below the cricoid cartilage, the other above it. The superior thyroideal artery was too high to be injured; the inferior thyroideal and the recurrent nerve were below, and on the inner side of the wound. The last-mentioned artery may undoubtedly be divided in the operation; this, therefore, is to be guarded against by a careful and deliberate dissection. The operation has not been performed in some cases where it ought to have been. Mr. Arnott thinks that the fact of its having been executed on a child two years and three months old, without injury to any important part, may prevent this omission in future.

The reading of Mr. Arnott's paper was followed by a short account, by the President, of a case of

"*Glanders in the Human Subject,*" tending to confirm the views given in his former paper, published in the Transactions.

A man, aged 23, but looking much older, was lately admitted at St. Thomas's Hospital, complaining only of general debility. After a few days he had diarrhoea, pain in the head, and pains of the limbs like rheumatism. A gangrenous

swelling appeared on the hand, and another on the foot. He became delirious, and required to be secured with straps. There was much swelling about the back of the head, and tumefaction and gangrenous redness also shewed themselves about the nose and temple of the right side; fetid discharge from the nostrils; swellings on the extremities were developed, livid or red, fluctuating, and of various sizes. It was ascertained that he had been exposed to contagion from a glandered horse of his master's, and no doubt was entertained of the nature of his complaint. He died after a few days, in a state of violent delirium, and the body was examined in the presence of several practitioners; the case having excited much interest. The external tumors were found to contain a yellowish glairy fluid, with portions of purulent matter intermixed. In one of the frontal sinuses was found a soft tuberculous or vesicular mass lying loose in the cavity. On the right side of the septum nasi were two minute ulcers, with injection of the surrounding membrane. The edge of the ulcers was elevated, and supposed by some present to resemble the glanderous ulcer in the horse. At the lower part of the larynx there was an ulceration still more resembling that of glanders, having abrupt elevated edges. The mucous membrane of the air-passages generally was inflamed, and contained a certain quantity of purulent matter. No other conspicuous lesion was observed.

[A full account of the cases observed by Dr. Elliotson, and of all that is known upon this curious subject, will be found in a lecture by that gentleman, inserted in the *Medical Gazette* for December 15, 1832, pages 338, et seq.]

Tuesday, March 26.

The first part of a paper by Mr. Humphry Sandwith, "*On the Theory and Treatment of Scarlet Fever; with brief notices of the disease, as it prevailed epidemically at Bridlington, in 1831,*" was read by the Secretary.

After some elaborate introductory remarks on the mortality of this and other diseases which prevail epidemically, the author proceeded to speak of the appearances it had assumed under his own inspection. As, however, the reading was interrupted before the subject had been completed, we think it better to postpone our account of it till we shall have heard the whole.

After the paper had been read,

Mr. Stanley called the attention of the meeting to a bottle preparation which he held in his hand. Since Mr. Hilton's paper was read to the Society (*Med. Gaz.* vol. xi. p. 605) he (Mr. S.) had met with a quantity of indubitable hydatids in the

voluntary muscles of a subject dissected at St. Bartholomew's. They were of the kind so well described by Rudolphi, and consisted of the usual globular or ovoid cyst, containing the body and the head, when not protruded. Those in the preparation were, some of them, larger than a good-sized pea.

Some conversation afterwards arose on the subject of *phlebotomies*. The subject was introduced by Dr. R. Lee. Mr. Stanley was inclined to think that those curious bodies were simply a deposit from the blood itself, and not a secretion from the coats of the veins. He had frequently met with them, and bestowed on them a good deal of his attention; and he cited a paper which appeared in the *Medical Gazette* in the course of last summer, as containing some excellent remarks on the subject. Mr. Partridge made some observations to the same effect.

The paper to which Mr. Stanley alluded, will be found in the *Gazette*, vol. x. p. 515.

The meeting was very thinly attended; and that of the 12th was not much better.

MEDICO-BOTANICAL SOCIETY.

Tuesday, March 26.

Observations on the History of Oxalic Acid as a Poison.

DR. CLENDINNING delivered a lecture on this subject this evening. He began by tracing the earliest notice of oxalic acid as a poison which is to be found in the journals; and Mr. Royston's paper, in the *Medical Repository* for 1814, he thinks is the first. Afterwards, Drs. Christison and Coindet gave a full account of the acid in the 19th vol. of the *Edinburgh Journal*; and in the year 1828, Dr. Pommer, in the *Salzburg Med. Chirurgische Zeitung*, wrote an elaborate paper upon it. Oxalic acid is widely diffused through the vegetable kingdom: besides being found in very many common plants, it is to be detected combined with lime in several barks; and in a variety of lichens of the crustaceous kind, in which it seems to serve the same purpose as the phosphate of lime in animals. Rhubarb is said to contain 30 per cent. of oxalate of lime. But the only plant that appears to hold the acid uncombined is the chick-pea, which forms an ingredient in the famous dish—the *olla-podrida* of the Spaniards. In commerce the acid is procured by distilling nitric acid off animal and vegetable substances. The lecturer then proceeded to notice the physiological effects of the poison. When taken in a large dose, gastritis, of the most

excruciating kind, is produced, with sudden depression of the heart's action, terminating speedily in death. The mucous membrane of the stomach is found inflamed and gangrenous; but the intestines seldom suffer much. If taken in a very diluted state, the mode of action is different—but not less, if not even more, fatal than when it is swallowed in a more concentrated form. Death in this case is attended with tetanus or coma. With regard to treatment, the remedy which should be instantaneously employed is magnesia or chalk, suspended in water: in default of this, the stomach-pump. If gastritis, or the other symptoms just mentioned, have set in, treatment suited to the occasion must be actively adopted. The chemical history of oxalic acid next engaged the attention of the lecturer, who pronounced (*par parenthese*) a high eulogium on the pursuits of modern chemistry, and then turned to the medico-legal consideration of his subject. After noticing the physiological and moral proofs, he treated the chemical at some length. He gave an account of the several tests—the muriate of lime, sulphate of copper, ammonia, and nitrate of silver; and concluded by describing the process by which the acid, if mixed with organic substances, may be separated and tested apart.

The lecture was illustrated by preparations of the various stages of the experiments alluded to. Among the phials which Dr. Clendinning exhibited were two, one of them containing crystals of oxalic acid, and the other mixed Glauber and Epsom salts: the difference between them could scarcely, if at all, be distinguished by the eye.

ROYAL INSTITUTION.

Friday, March 22.

Improvements in the Manufacture of Salt.

MR. CARTMAEL, a practical man, gave some important information on this subject. One of the most striking modern improvements in salt-works is the introduction of very large pans: in one manufactory the extent of panning is said to measure three miles in length, by eight feet in width. The means adopted in order to avoid "pan-scratch," or the rapid destruction of the iron boilers by the fire, now go hand in hand with economy of the fuel. The fire is now applied only to a part of the pans, and the steam here generated is conveyed through a pipe in the top of the cover to other parts of the works. The bottoms of the boilers are

concave where they are exposed to the fire, and thus the earthy matter in the interior, causing pan-scratch, is avoided. The hot water is economized for warming fresh brine, and the surplus heat of the flues is saved in the stoving-house, for drying the manufactured salt.

Friday, March 29.

Mr. Brunel's mode of constructing the Arches of Bridges.

Dr. Faraday, who undertook to explain Mr. Brunel's principle, rendered it a subject full of interest to a very large audience. The chief advantage that would seem to attend the proposed method, is the saving the expense of constructing pile-work for centering: Mr. Brunel requires none. Nothing can be more original or characteristic than the mode in which his arch is literally built out into the air, without any support except from the cohesion of the materials and the counterpoise on the piers. The plan has not yet been put in actual practice; but a most satisfactory specimen of what it can effect is to be seen at Rotherhithe, where Mr. Brunel has constructed two half-arches, from 40 to 50 feet in length each, and balancing each other on a single pier. Dr. F. gave a comparative statement of the mode of erecting, the endurance of pressure, the expense, and other remarkable particulars connected with the most celebrated bridges in this and other countries.

HOTEL DIEU.

CLINIQUE ON DISEASES OF THE EYE,

By M. SANSON.

AMAUROSIS.

SOME have attempted to describe various shades or degrees of this under distinct names, and have called the weakened vision so common in aged persons *amblyopia*, while complete loss of sensibility has been called *amaurosis*. These distinctions appear useless; and it is more simple to consider the impaired sight of old people as the first stage of amaurosis. The Germans have imagined that there are as many different kinds of amaurosis as there are causes; thus they admit one kind for inflammation of the retina; another for suppression of the milk; another of *eroryza*, &c. M. Sanson, in rendering justice to the labours of the Germans in this department of surgery, pointed out the inconvenience of these subdivisions, and endeavoured to arrange the subject according to a less extended but more perspicuous plan. Thus, according to the Professor, all

causes of amaurosis, of whatever kind, act either upon the retina, or on the optic nerve, or on the brain.

With regard to the anatomical characters, the retina often presents alterations of texture; it is found thickened, wasted, dense, cartilaginous, or ossified, in whole or in part. Its colour is usually of a greenish opal; sometimes of a greenish grey; sometimes it is detached from the choroid: sometimes there are found sanguineous or serous effusions, or cysts, between these two membranes. Lesions, however, are much more frequently met with in the optic nerve than in the retina; thus it is found broken (*rompu*), softened, atrophied, and compressed by tumors—particularly by exostosis, polypi, tubercles, &c. Its consistence is also subject to change; it may be hard or friable, and it may be changed as to colour, all of which lesions may occupy the entire nerve, or only part of it. Anatomy still leaves the crossing of the optic nerves a matter of doubt. Sometimes we witness the nerve corresponding to the amaurosis wasted from its expansion in the retina to the sella turcica, and the nerve of the opposite side from this point to the brain; sometimes both the optic nerves are wasted, while there is, besides, a yellowish tint of the amaurotic side both before and after the union of the nerves. The question of decussation therefore remains still in doubt.

The lesions remarked in the brain are, abscess, serous or sanguineous effusions, or simply signs of irritation. At other times the amaurosis is only sympathetic of the development of tumors in the brain; and slow compression of the organ from any cause may likewise cause this affection. In some cases it must be confessed that no anatomical lesion of the encephalon is found by which the amaurosis can be explained.

Amaurosis is *idiopathic*, *sympathetic*, and *sympathetic*. The causes are divided by M. Sanson according to their effects, and constitute two great classes—*sthenic* and *asthenic*. But these two are each subdivided into three species, thus:—1, causes acting directly upon the retina; 2, causes acting upon the brain; 3, those depending upon some organ more or less distant from that of vision. Finally, there exists another set of causes not included in the above, and the *modus operandi* of which is not explicable in the present state of medical science. The *sthenic* are more numerous than the *asthenic* causes.

Among the *sthenic* causes acting directly upon the eye, and producing amaurosis by direct irritation of the retina, are ranged—all kinds of ophthalmia—san-

guineous congestion of the eye—penetrating wounds of the eye, or contusions (as from a pellet of lead, which, by producing a commotion of the globe of the eye, may give rise to a pure and simple amaurosis) and the presence of a foreign body in the orbit. The affection has been met with from a blow on the cheek—from bright light—inflammation of the retina—long-continued inspection of minute objects—the habitual use of optical instruments—the impression of irritating gases.

The causes affecting the retina and brain indifferently are said to be—the suppression of any natural or morbid process, as of hæmorrhoids—epistaxis—the omission of an habitual bleeding—the retrocession of an exanthematous eruption—suppression of the menses, milk, &c.—of the discharge from a blister, moxa, &c.; and, finally, insolation long continued.

Among causes acting directly on the brain, and which may in the end produce amaurosis by asthenic action, we find apoplexy—prolonged study—violent passions—want of sleep—intoxication—baths used too warm—wounds of the brain—concussion, &c.

The causes producing amaurosis sympathetically are, an acute or chronic inflammation of the alimentary canal—the presence of intestinal worms—colic from lead—calculi of every kind—difficult menstruation—troublesome pregnancy—poisoning—syphilis, or rather gonorrhœa—rheumatism—difficult dentition—all acute diseases which affect the brain, and also some of a chronic nature.

Among the asthenic causes operating upon the retina, are enumerated the employment of certain medicines, such as extract of belladonna, the exact effect of which is still a matter of doubt; and the complete exclusion of light. When the retina is prevented from exercising its functions for a longer or shorter period by the presence of a cataract, it may gradually lose its natural sensibility, so that the patient continues amaurotic even after the operation of a cataract. Asthenic causes are abundant hæmorrhages, venereal excess, masturbation, old age, great agitation, fear, narcotic poisons.

First among the causes not enumerated with the preceding, and the action of which cannot be determined, may be placed hereditary disposition. M. Sanson attended a family, composed of a father and four children, all of whom became amaurotic at the age of twenty. Beer mentions a case in which a woman became amaurotic for a time as often as she made use of chocolate. What are we to think of the history of a woman who from the third to the fourth month of her pregnancy

became amaurotic on two successive occasions. Blue eyes, according to the same authority (Beer) appear not to be liable to this affection, a proposition not without some foundation, for of fifteen cases of amaurosis admitted at the ward St. Jeanne since the 15th February, two-thirds had black eyes. Cutting the hair or beard may also, according to Beer, produce amaurosis.

As to the characters and varieties of amaurosis, the complaint is either slow or rapid; and in this latter case, it is almost always in the morning that the patients find themselves affected by it. It may be single or double, congenital, or occurring from old age; complete or incomplete; partial or total; it is also transient or permanent, recent or old, continued or periodic. Amaurosis generally affects both eyes at once, and always consecutively.

The symptoms may be divided into those furnished by the patient—*subjective* signs; and those observed by the surgeon, *objective* signs.

The patient usually experiences more or less headache, accompanied by vertigo and somnolence; he has a feeling of pain in the eyes, after which the vision becomes weakened. He perceives external objects indistinctly through a kind of network formed of threads of various colours—light and brilliant; at other times he sees a number of specks, and spots of different forms and shades. These lines and spots are fixed; that is to say, they always maintain the same position with respect to the axis of the visual rays. These are the subjective signs.

The signs perceived by the surgeon are more numerous, and more positive; they are as follow:—The iris is motionless; sometimes, but rarely, it retains its contractility. In order to judge accurately of the iris, it is necessary to keep the other eye closed; for when this one is sound, or but slightly affected, the influence of the light upon it is communicated by sympathy to the iris of the other side, so as to produce its contraction. The pupil is more or less contracted, and for the most part is perfectly black; sometimes, however, the colour is greenish, or even whitish; the eye placed in the shade sometimes exhibits a brilliant reflection, similar to that seen in cats examined in the dark. The bottom of the eye is occasionally marked with irregular spots. In some rare cases the pupil is contracted. The patient seems to squint; his look is confused and expressive of hesitation, so that one may form a strong presumption as to his complaint, even looking at him from a distance.

The progress of the amaurosis is either slow or rapid—sometimes requiring seve-

ral years to attain its full development. When it is neither sudden nor violent, there are intervals of mitigation—a distinctive character, which serves to distinguish it from cataract; for in this, vision is lost progressively, and without those alternations. In some instances the affection only lasts a few minutes, particularly where it is sympathetic; it then disappears with the cause which had given rise to it; but its duration is uncertain when it is symptomatic or idiopathic.

The diagnosis of this disease is not always easy; for if it have many signs proper to make it distinguishable from certain other affections, there are also those which may lead to error; and it is those which it is necessary to establish thoroughly. We have already said that the immobility of the pupil—its ordinary dilatation—its black colour—the transparency of the eye—the dulness—the weakness of sight—the inconstant contraction of the iris, and its irregularity, were the most prominent characters of amaurosis. Nevertheless, it is proper to observe, that in paralysis of the iris the pupil may be immobile, while the retina retains its sensibility in whole or in part. The irregularity of the pupil when it is immobile, is sometimes dependent upon partial adhesions of the iris to the membrane of the crystalline lens. The colour of the pupil may serve to distinguish it from incipient cataract; for this black, or clear, or greenish, or whitish, appearance occupies the fundus of the retina, and presents a corresponding concavity; while in cataract it is on a plane anterior to the other, and exhibits a whitish or cloudy appearance. The opacity is in direct proportion to the diminution of vision. Some patients have the sensation of a cloudy whiteness when they are in the dark. Strabismus may take place in simple amblyopia, and may also be simulated. The peculiar dulness of aspect only occurs in complete amaurosis, and is its constant sign. Generally, when the patient sees round any light a whitish areola, it is a symptom of cataract; but if the areola seems iridescent, it is indicative of commencing amaurosis. A black cataract may be confounded with amaurosis; but this affection is rare. Besides, on examining the parts in profile, we remark, sufficiently distinctly, that the pupil presents a metallic reflection similar to that of bronzed steel: and, again, its progressive march, so different from the irregular course of amaurosis, may serve to facilitate the diagnosis. In cataract, also, the patient sees spots and lines fixed, or mobile; but amaurosis may yet be distinguished from this affection in that, in cataract, an opacity more or less developed in the crystal-

line or its membrane may be perceived. The individual having cataract, often distinguishes objects less in bright light than in the shade. The diagnosis between incipient glaucoma and amaurosis is very difficult at first; but soon the patient experiences dull pains, deep-seated, and then lancinating; while, finally, formidable changes manifest themselves in the eye; which does not happen in simple amaurosis.

The prognosis in this complaint is not unfavourable, considered with respect to its influence on the system generally,—unless, indeed, the loss of sight produce a serious depression of spirits, in which case the patient will probably sink slowly and gradually. But it must not be denied that the prognosis is always lamentable, depriving the individual as it does of a precious sense, it being extremely difficult to treat successfully, and, if this have been done, still more rare to prevent a return of the disorder.

[To be continued.]

LECTURES AT THE COLLEGE OF SURGEONS.

MR. EARLE will commence his lectures, at the College of Surgeons, on Tuesday next, April 9th.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE NECK AND
THROAT.

—
TONSILITIS.

WE now, gentlemen, enter the air passages; and the first disease of which I will speak is Inflammation of the Tonsils, called by Cullen *cynanche tonsilaris*, but frequently called by others *tonsillitis*.

Symptoms—The disease, however, to which this name is given is not an inflammation of the tonsils simply, but the surrounding parts are also more or less affected. The velum pendulum palati and the uvula, as well as the tonsils, one or both, are red and swollen. The uvula is elongated, and its margins are translucent; it becomes oedematous and swollen. If both tonsils be inflamed, on opening the patient's mouth you will see two large red balls, one on each side of the throat, which impede deglutition and speech, and may be felt also externally. When the tonsils are enlarged, people in common language say the almonds of the ears are down; they are called, in common language, "the almonds of the ears." Besides this swelling and redness, the secretion of the parts is altered, so that the mucus of the mouth is very tenacious—slimy, as people say. There is frequently very great pain; for the inflammation affecting the tonsils is of a phlegmonous character, and the pain is sometimes very severe, stabbing and shooting to the ear. Besides the shooting pain, there is necessarily great

tenderness felt, particularly on swallowing. Even the effort to swallow the saliva—that is to say, the mere effect of swallowing, without the presence of any firm substance to swallow—gives pain; the motion of the part is productive of pain. You may see the disease sometimes on one side only, and sometimes only on the other; and it is said that the disease will shift from one tonsil to the other, just as is sometimes seen in inflammation of the eye: when one eye gets better, the other will become inflamed; and this is often perceived in the case of the tonsils; when one ceases to be inflamed, the other becomes so.

Sometimes, in addition to the inflammation producing redness, heat, swelling, and hardness, there is a little ulceration—specks of ulceration. Some persons, as soon as they have a sore throat, have specks of ulceration here and there on the tonsils and uvula, with very little subjacent inflammation. Some persons have the mucous membrane only inflamed; the inflammation is quite superficial; perhaps without any inflammation of the subjacent cellular membrane, hardness, or enlargement. If the case be severe, there is a good deal of pyrexia. The pulse will become very quick in this disease, as it sometimes will in acute rheumatism, without any danger whatever; and the tongue is frequently excessively foul; I presume from the inflammation affecting it as well as other parts. The foulness of the tongue is not at all in proportion to the danger of the disease; but I presume it arises in a great measure from the irritation being situated in that quarter of the body.

Termination.—The disease may terminate in resolution, as it is called, or it may terminate in suppuration. It is decidedly phlegmonous inflammation, so far as the parts are concerned, and they very frequently suppurate; and when they do, the matter is found to be very offensive—as offensive as if it were coming from a diseased bone.

Predisposing Causes.—The predisposing causes to the disease are, in the first place, a peculiar constitution and disposition to it. There are some people who, in whatever way they are exposed to the general causes of inflammation, continually get a sore throat. Whenever they are exposed to the vicissitudes of temperature, coldness, and moisture, they are sure to have inflammation of the throat; and this will run in families, so as to be constitutional. It certainly is predisposed to by mercury. When persons have been much under the influence of mercury, they are very liable, as I formerly mentioned, when speaking of inflammation in general, to take cold from the vicissitudes of temperature, and the throat is certainly particularly liable to inflammation from this cause. The youthful period of life appears more liable to tonsillitis than old age: we see far more cases of inflammatory sore throat in the young than in the old.

Exciting Causes.—The exciting causes of the disease are, especially, cold and wet, whether applied to the body at large, or to the feet only. Perhaps, among the predisposing causes, I might have mentioned the season of the year—spring. Certainly cases of this description occur from cold and wet more frequently in the spring than at any other period of the year. Cold and wet united are common causes of the disease. Cold applied in any way is sufficient to produce the disease.

Treatment.—In regard to the treatment, it is rarely necessary to take any blood from the arm; but leeches around the throat are particularly useful. I do not know that it is necessary to apply them internally to the fauces; I think that externally they answer every purpose they can do, and that a free application of leeches is far before blistering. As a general rule, in the treatment of inflammation we must be upon our guard never to let blistering take the place of the removal of blood. If the inflammation be at all severe, you only harass a patient in any inflammation whatever by blistering, if there be a necessity to take away blood; and in this disease blistering is a very painful remedy. A blister produces great anguish when applied to the throat, and does not answer by any means so good a purpose as leeches—the frequent application of leeches externally under the lower jaw, followed by poultices. The application of poultices not only tends to encourage the bleeding, but is a constant fomentation, a mode of relaxing the parts, and causing perspiration there. If the patient be too weak for you to apply leeches, a blister then will be proper; or, if you have applied leeches as much as you think advisable, and still it is requisite to do more,

before the disease can be controlled, then blisters may be used with advantage. It must, however, be remembered, that when a patient can bear leeches you find them the most useful.

I have found great benefit in this disease from a mode of treatment perfectly analogous to what is practised with so much success in some cases of inflammation of the surface of the body and subjacent cellular membrane. You know that, in erysipelas phlegmonoides, or any kind of erysipelas where there is extreme tension and hardness of the surface, incisions do great good; they set the surface at liberty—allow it to gap, so that the tension is removed, and great benefit always ensues. Now I have adopted similar treatment frequently in inflammation of the tonsils, and with very great effect. It is sometimes very difficult to know, in the case of the tonsils, whether matter is formed or not; and I dare say many practitioners—I am sure it has occurred to me—have plunged a lancet into the tonsils, in the expectation of finding matter, when there was none. They become sometimes so exceedingly large that it warrants a person in trying whether there is any matter or not. Sometimes, when there is matter, instead of being softened, the parts are so tense that you will not find any fluctuation; and sometimes they are swollen so much that you would fancy there was fluid when there is not. Thus mistakes are made on both sides. But whether matter comes or not, great relief is experienced by plunging a lancet into one or two places. The part is always very tense; if you put in a lancet it gapes; and when there is a little bleeding the patient in most cases is better for it. I have seen it afford far more relief than leeches; and I know, therefore, that it is a very good practice to put a lancet in for the purpose of making an incision in the tonsils. If there be any matter there the escape would be desirable; but if there be none you generally find very great benefit.

For the purpose of purging there is nothing so good as a large dose of calomel, because it may be mixed with sugar and put on the tongue, and it slips down easily. It is wrong to give acrid purgatives, such as salts, which stimulate the parts as they go down; and it is wrong to give anything bulky;—castor oil easily slips down.

Some persons recommend vomiting in this disease, and certainly it causes a great discharge of mucus from the pharynx and larynx, and all the surrounding parts, and frequently does good; but frequently it is a severe remedy. I believe the free application of leeches externally, an incision or two in the tonsils, and a good dose of calomel, for the most part cure the disease.

Gargles are pleasant to the patient, on

account of the tenacity of the mucus. A sour gargle is very grateful, and so sometimes is the inhalation of the steam of hot water. This relaxes the parts, and is found very agreeable; but I have often seen patients derive the greatest comfort from ices.

As to starving and low diet you need not inculcate it, for the patient cannot swallow any thing. As soon as ever you are satisfied there is fluctuation, as soon as you feel the parts soft, or if the part have been inflamed some days, and continues large, it is always right then to make a puncture. If you do not choose to make a puncture to lessen the inflammation, still it is right to do it on the probability of there being matter, not only as soon as you feel fluctuation, but when several days have elapsed, and the part is swollen. It is wrong ever to delay this operation; it is quite harmless, and only productive of momentary pain.

Although this is the form of the disease which we see every day, yet we occasionally find this affection occurring with debility. It is chiefly in old people that it occurs in this latter form, and chiefly in people who have had frequent sore throats. When the throat has been sore very often, the inflammation is not of an active kind, but follows the course of gonorrhœa:—when people have had that affection very often, the active symptoms are less severe, and so it is in the throat. When persons have had many attacks of tonsilitis, the inflammation is generally less active; the parts are not of so bright a red; they are of a more dingy red, there is less pain, and the swelling is greater in proportion to the other symptoms.

In such a case as this, with such debility of constitution, the shortest way is to give stimulating gargles; for instance, the American decoction of seneka, with Cayenne pepper and brandy in it. If the patient be weak, you must give good food, and sometimes allow a little wine. The case may be like any other inflammation—active, and to be treated as first pointed out, or it may be passive, and require only local astringents and stimulants; but sometimes the whole constitution is weak, and you have to support the patient with good food, and perhaps even wine.

Tonsilitis, attended with Ulceration.

It is when this disease occurs with ulceration that treatment of this kind is most frequently required. Sometimes, when the disease occurs with ulceration, there is a great tendency to mortification.

This is a case that must be treated on the principles I before mentioned—good food, more wine, and perhaps quinine. But good food and wine are among the best things; and you must also employ

stimulating applications, together with stimulating gargles. In this case, too, the chlorides of soda and lime answer very well; that is, when the patient requires a stimulating gargle simply.

It is not, however, in every case of inflammation that you are to presume there is ulceration; but, as I mentioned when speaking of ulceration of other parts of the body, where there is ulceration you must adopt antiphlogistic regimen. Many cases of ulcers of the leg have I seen yield to antiphlogistic treatment after all other means had failed; and so it is in ulceration of other parts of the body. You see the parts red, and there are signs of strength, and the shortest way to cure the ulceration is to bleed locally and generally, and put the antiphlogistic plan in force. Ulceration, however, occurring in the throat is most frequently of an opposite character. This ulceration of the throat is most frequently seen in scarlet fever, where it is called *cynanche maligna*; but frequently ulceration of the throat occurs without scarlet fever at all.

Under these circumstances, it is frequently necessary to inject stimulating gargles several times a-day. One of the best applications is the acetate of copper made into a gargle. There are many good ones, but this is one of the best.

Chronic ulceration, also, of these parts is very common. It is, you know, one of the common effects of syphilis.

Enlargement of the Tonsils.

But, besides this, the disease itself (to say nothing of inflammation in other parts) is sometimes chronic, and it is then attended with permanent *enlargement of the tonsils*. This is more frequently seen in children than others. The tonsils, after they have been inflamed, remain hard, fall into a state of chronic inflammation, induration, and enlargement—from lymph, I presume, having been effused into the cellular membrane. There is no difficulty, in cases of this description, in making a diagnosis. If you fail to make it externally, you have only to make the patient open his mouth and you see the disease.

Treatment.—The best treatment is the moderate exhibition of calomel, so as slightly to affect the mouth; the use of iodine, internally or externally; and hydriodate of potassa. Iodine, in both forms, has great power in dissolving and dissipating induration and enlargement. There can be no impropriety in combining both plans together. If there be much tenderness, leeches are very proper.

Occasionally this enlargement is not the result of active inflammation, but takes place slowly; and friction with iodine, or

hydriodate of potassa, or both, is a very good thing. Sometimes you will see cases in which it is judged right to have recourse to surgery, to extirpate the tonsils, or tie a ligature; but the greater number of cases do not require this, provided you treat them early and perseveringly by mercury, or iodine and hydriodate of potassa, both internally and externally.

Fætid Breath.

Speaking of diseases of the tonsils, I may mention, that sometimes persons are consulted on account of the patient having a fætid breath, commonly called, in vulgar language, a *smoky chimney*. It must be very annoying if people are married, or even in the way of being married; and I have no doubt that it has frequently prevented that interesting ceremony from taking place.

Causes.—Now a fætid breath may arise from many causes. It may be accidental, from a person eating something nasty, and which enters into the blood, and is there poured forth, till the blood gets rid of it all, from the vessels of the bronchiæ. If a person eat onions, it is not while they are in the stomach that the breath is fætid; but when the odorous principle of the onions is in the blood, it is poured forth into the bronchial membrane. The bronchial membrane is found, by physiological experiment, to be one of the great outlets by which the body gets rid of improper things taken into the blood, or, at least, of things foreign to the blood. Carious teeth, or a diseased bone, is likewise a cause of fætid breath; but one very common cause is a depraved secretion of the tonsils. If you look into the mouths of these patients, you will frequently see the tonsils enlarged, one or both, or at any rate you see them containing a cheesy-like matter; and if it be pressed out with the handle of a spoon, the person's breath, for the time, is so much the less offensive; but the individual's breath itself, independent of this stuff, may be offensive.

I should imagine that stimulating the follicles to a greater secretion would favour the escape of this stuff, and not allow it to accumulate there, and form these nauseous concretions.

Pustules on the Tongue, Lips, and Cheeks of Infants.

You will repeatedly have children brought to you by their mothers with pustules on the tongue and lips, and inside the cheeks. I do not know that the disease has any specific name, but the tongue, sides of the cheeks, and lips, are elevated in consequence of the pustules, and the tongue is frequently much swollen, and just the colour that it is when persons are much under the influence of mercury. You

would imagine at first sight, from the swelling of the tongue, the quantity of mucus secreted, the saliva running out of the mouth, and the fætid state of the breath, that the child had taken mercury; but if you give calomel in such a state as a purgative, (and which is one of the best things to give to children), it does not increase the mischief, but answers well as a purgative.

Treatment.—I have found great benefit in these cases from the use of washes containing some astringent; but the best mode of giving it to the child is to put a grain or two of sulphate of zinc, for example, into an ounce of syrup. The child has no objection to it, and it exercises a beneficial influence. The disease sometimes occurs to many children in one family; but whether it is contagious I do not know. The disease is described as common ulcers on the mouth of children, and they may last some time without any danger, but purgatives and local astringents are very useful. Whenever you have to apply an astringent to the mouth of a child, it is best to give it in syrup, instead of water.

APHTHÆ.

There is a disease that affects these parts frequently and usually in the period of infancy, which is called the *thrush*, or, in medical language, *aphthæ*. It is mentioned always under diseases of the skin; but as it occurs in the mouth and throat, it is perhaps hardly right to call it a cutaneous disease—it is a disease of the mucous membrane.

Character.—However, this disease, aphthæ, consists in the formation of vesicles within the mouth and lips, and all the way along the cheeks, tongue, the *velum pendulum palati*, even the mucous membrane of the hard palate, the tonsils, and pharynx. On opening the mouth, you see just the appearance as if the patient had been taking milk curds and whey, or some chalk mixture: all the vesicles are exceedingly white. This is produced by innumerable elevations of the cuticle, by a fluid, and a large number of minute vesicles. There is sometimes a good deal of inflammation with it, and sometimes you will see scarcely any thing more than this white appearance, as if the parts were filled with curd.

Frequently conjoined with other Diseases.—It certainly is the most common in infants, but you will frequently see it in adults, at the end of chronic diseases, at the end of phthisis. It is very common for persons then to complain much of the throat, to complain of a difficulty of swallowing, and even when persons die of diseases of the abdomen of various sorts, it is very usual indeed to see aphthæ before death. It will

occur in old people, from very trifling causes.

Not necessarily fatal in old people.—Now this is supposed to be a fatal disease when it occurs in old people, or in those in whom a chronic disease has existed for a long time; but it is not an invariable rule. I recollect an old lady of 90; she was so old that nobody thought of saying how old she was; she had been ninety so long that nobody continued to add the odd years, just as is the case in horses; and she was the wonder of the village. At that advanced age she suffered an attack of bronchitis, and got well, and afterwards attained the age of 100; how much more I cannot tell; but I know she lived ten years after the attack, notwithstanding it was united with aphthæ, and therefore aphthæ is not a fatal sign in old people. You however see the disease every day in persons who are dying of chronic diseases. I believe old women say that you must have the thrush first or last; that if you do not have it when you are young, you must when you are old. I only mention this to shew how common the disease is.

Treatment.—Now when the disease occurs in infants, it may be so slight as to require scarcely any treatment; but if it do, you find it useful to employ the warm bath, and attend to the bowels. There is frequently irritation of the mucous membrane lower down in the alimentary canal, frequently sickness, and frequently diarrhœa; and you therefore frequently find it useful, besides the warm bath, to have recourse to purgatives, and besides that, it is sometimes necessary to employ hydrarg. c. creta and opium. There is often tenderness on pressure, and then it is necessary to apply poultices over the abdomen, as a constant warm bath, and to apply a leech or two, but often a mustard poultice answers best. A small portion of ipecacuanha, or camphor, is often serviceable, but nothing is better than a mild astringent in syrup, such as I have mentioned already—a minute quantity of sulphate of zinc, for example. Many people employ borax and honey; and old women tie a rag to a stick, and mop out the child's mouth, and thus make things worse—they had better use a camel's hair pencil, or leave the disease to pursue its course. I have no doubt that in children the chlorides are useful, but of course they must be given very much diluted. In adults I do not know any means so useful as the chlorides; they will frequently change the appearance of the mouth almost immediately; but they require to be well diluted—the common solution must be diluted with six or eight times its weight of water. When the intestines have been in a state of irritation only, a few specks will appear at the

rectum, and then old women consider that the disease has had a long journey, and shewn itself at the other end. If, however, you look into the intestines, you find no inflammation, only specks, but it is only towards the anus that the specks appear; nevertheless, the irritation which produced the vesicles certainly does frequently extend all through the alimentary canal.

EAR-ACHE.

Before I quit these parts, as we are so near the ear, which communicates with them by the eustachian tube, I must direct your attention to what is commonly called *ear-ache*, not because it is an important disease generally, but sometimes it is of very great importance.

You will recollect I mentioned, when speaking of inflammation of the brain, that it will spread from the ears and eyes. I have seen several cases of phrenitis which have spread from the ear. Common ear-ache is not a thing so free from danger as tooth-ache; we every day see ear-ache, and think nothing of it when persons complain, but in any case it may be dangerous.

Treatment.—Ear-ache always arises from more or less inflammation in the meatus auditorius, and ought always to be attended to. Leeches should be applied externally, and blisters, and in some cases the patient should be bled in the arm. After it has lasted a long time, the bones frequently become carious, and when the bones are carious within, inflammation of the dura mater lying upon the petral portion of the temporal bone is likely to come on, and then it is all over. You will find, after death, matter formed within the ear itself; but you find it also formed upon the bone under the dura-mater, and perhaps above the dura-mater—in the arachnoid, and various other parts; perhaps on the pia-mater, and other parts of the head, encephaloid disease and other affections take place, the patient becomes delirious, and is soon gone. Therefore, when you see intense ear-ache, and the patient complains of pain in some other part besides the ear, and you observe a wandering of the eyes, it is well to tell the friends that he is in the greatest danger.

Of course, such a case ought to be treated, like other cases of phrenitis, actively, but I believe in almost every case you find all treatment unavailing. There is a local cause keeping up inflammation of the part, that is to say, disease of the ear, and you cannot expect to be successful.

PHARYNGITIS.

There is also inflammation of another part, very far back, which is spoken of by Cullen, and I therefore legitimately

touch upon it, viz. pharyngitis, inflammation of the pharynx, or, as it is called by Cullen, *cynanche pharyngea*.

Symptomatic and Idiopathic.—Pharyngitis usually takes place from the mere spread of inflammation from the tonsils: when the tonsils are inflamed, it is very common for the inflammation to go farther back. Inflammation knows nothing of our artificial division of organs and division of diseases, but away it goes along the mucous membrane, and the pharynx is continually inflamed. Now and then, however, we have it in an idiopathic form, that is to say, it occurs as a distinct separate disease, not coming on with any other disease. I have myself seen one or two instances of it.

Symptoms.—When this inflammation exists there is redness at the back of the throat; on looking into the mouth you see the posterior part exceedingly red. Respiration is not at all difficult, as you might suppose; but deglutition is very much impeded. The voice is not affected any more than respiration; at any rate, if there be any difficulty of respiration, it is slight. It is the gullet that is affected, and therefore persons can speak and respire very well.

Treatment.—With regard to treatment, it is the same as that for inflammation of the tonsils, and therefore I shall not dwell upon it.

STRICTURE OF THE ŒSOPHAGUS.

We are frequently consulted upon a disease rather lower down than the pharynx—that is to say, stricture in the Œsophagus, producing obstruction.

Symptoms.—In this disease there is, as in inflammation, a difficulty of deglutition; but then there is no sensation of heat in the part, no soreness, and for the most part, no pain. The difficulty of deglutition is chronic, and for the most part has come on very slowly.

It is easily ascertained by the application of a bougie or probang, and this, I may say, is the only remedy; for medicine can do no good in stricture of the Œsophagus. When patients come with a difficulty of swallowing, if you ascertain it is not in the throat, but a little lower down, and you find the stricture has come on slowly, it is right to pass an instrument down a certain distance. This being the case, you employ surgery, and surgery only.

But you will sometimes see this in a different form, and it is then entirely of a spasmodic nature. Frequently, when persons have not a permanent stricture of the Œsophagus, they have occasionally a spasmodic stricture in the part, just as they have in the urethra, so that it will be ten times worse at one time than it is at another.

SPASMODIC CONSTRICTION OF THE ŒSOPHAGUS.

Occasionally there is another symptom without any danger. You find the Œsophagus fall into a state of spasmodic constriction. This occurs more frequently in women than in other persons, and frequently it is connected with hysterical symptoms.

Treatment.—The best mode of treating it is to use the shower-bath; to purge the patient well; to use oil of turpentine, and all the remedies of that kind. I have read of cases where it appeared to give way to mercury, but I have not seen them myself; it has always appeared to me, that they would do better with the common remedies of hysteria—by purging, on the one hand, and lessening the irritability of the body at large, by means of the shower-bath, the administration of iron, and putting the health generally into good order, on the other. But you must carefully remember that the Œsophagus is very liable to spasmodic stricture without any danger at all.

ACUTE LARYNGITIS.

Not a new Affection, though omitted by Cullen.—I shall now proceed to consider inflammation of the commencement of the air-passages, properly so called—inflammation of the larynx—*laryngitis*. This disease is not mentioned by Cullen: he speaks of *cynanche trachealis*, he speaks of the wind-pipe and of croup, but not of this particular inflammation situated in the larynx. Indeed, so little was it formerly attended to, that when two or three physicians died of it, some years ago, it was considered almost a new disease; but on looking into old writers you will find it well described. As you may suppose, inflammation of the larynx must have existed from the time that people had a larynx, and therefore this disease must have been known before.

Symptoms.—In this affection there is hoarseness, or whispering, and, indeed, almost suppression of the voice. The breathing also is hoarse, loud, and rough. The inspirations which are taken are long. There is great dyspnoea, and, besides the constant dyspnoea, there are paroxysms of much greater dyspnoea, in which every muscle of the body comes into play, the eyes start, and the person looks as if he were being hung. These are spasmodic fits of difficulty of breathing, supervening from time to time on constant dyspnoea. Such is the state of the parts that there is also frequent orthopnoea—that is to say, the person cannot breathe unless he be erect. From the great difficulty of breathing, the face is pale and ghastly; the lips are pale and livid—not of a purple colour and livid, but pale and livid; and perhaps the

face and throat are swollen. There is pain felt in the throat exactly at the situation of the larynx, and if you press the larynx you are sure to find it tender—if you press the sides together, or press down upon it, you find it tender. Sometimes, but not always, there is redness and swelling of the face.

Sometimes there is swelling and redness of the fauces, of the velum pendulum palati, uvula, and indeed of the tongue. Occasionally, cynanche tonsillaris co-exists with laryngitis; indeed it frequently does so: the inflammation commences in the tonsils and spreads into the larynx. The epiglottis is very often swollen, that being a part of the larynx—so much a part, that it is, in many anatomical books, enumerated with the cartilages of the larynx. Sometimes there is cough, but not always, and with the cough there is hoarseness; so that you will have the voice hoarse, the breathing hoarse, and the cough likewise hoarse. Sometimes, too, there is difficulty of swallowing. In the function of deglutition, the larynx, you know, is raised and brought forward; and if a part of the larynx so much pressed upon be inflamed, of course there is a difficulty of deglutition—*dysphagia*, as it is called. There is also expectoration of viscid mucus. This you would suppose: the inflammation being seated in a mucous membrane, it will, of course, affect the secretion. The tongue, too, is very foul, from the inflammation taking place in its neighbourhood. These are the local signs; and they are those of inflammation, redness, swelling, heat, and pain.

From the disturbed function there are, of course, also general symptoms: there are thirst, heat, extreme restlessness, and great anxiety. The difficulty of breathing must occasion great restlessness, and must occasion extreme anxiety. The pulse is rapid; there is at last a clammy sweat; the pupils, too, at last become dilated, and the patient keeps his mouth constantly open. The difficulty of breathing occasions, I presume, such an accumulation of blood in the head, that more or less compression exists, and the pupils consequently become dilated; and the patient, from the want of breath, opens his mouth, gasps, and makes an effort to take in all that he can.

Duration.—This disease, when acute, lasts only about three or four days. I of course do not enumerate the previous days on which there may be cynanche tonsillaris; but from the time the larynx becomes actively inflamed, the duration is not, in general, more than three or four days; and death sometimes occurs very suddenly—a violent spasm takes place, and the patient is destroyed presently.

Usually attacks Adults.—This is a disease which occurs almost always in adults. In children we have croup—inflammation of the wind-pipe; but when inflammation of this violent kind attacks adults, it affects the tube higher up—it affects the larynx; and it has, therefore, been called the croup of adults.

Morbid Appearances.—After death, we find the mucous membrane of the glottis (and epiglottis especially), and the posterior part of the epiglottis—perhaps the mucous membrane of the whole of the larynx—red and swollen, and oedematous; swollen, not merely as mucous membranes are when they are inflamed, but from the effusion into the subjacent cellular membrane. The rima glottidis is found to be nearly closed, and this would appear to be the great source of dyspnoea—the oedematous state of the parts which produces nearly a closure of the rima glottidis.

Sometimes the disease proceeds so far as to cause an effusion of fibrin; so that notwithstanding the disease is an affection of the mucous membrane, fibrin is poured forth just as we see in a serous membrane; and sometimes we find a quantity of pus—at least of puriform fluid. Occasionally the tonsils are not merely red, as I stated, but even ulcerated; and occasionally the pharynx and the trachea below, and even the bronchiæ, are also inflamed. You are therefore not to expect one uniform appearance in the disease. You will find the essence of it, in all cases, to be a violent inflammation of the larynx, and, in general, an oedematous state of the rima glottidis and the parts around; but frequently you will find inflammation higher up, about the tonsils and the velum pendulum palati—inflammation, perhaps, also of the pharynx. With respect to the quality of the fluids, they will vary from thick mucus to puriform fluid, and even up to fibrin; but that which you particularly notice is an oedematous state.

Now all the symptoms are nothing more than you would expect before-hand. The oedematous state, which perhaps is fatal, is nothing more than what occurs when the cellular membrane is inflamed any where. When inflammation is situated near cellular membrane, it secretes abundantly. In violent inflammation of the skin, the cellular membrane secretes to a great extent, and you have more or less oedema; and the same thing occurs here; but from the circumstance of the parts being air-passages, and the inflammation being in the narrowest part of the passage, it is often dangerous. The same occurrence, situated a little higher in the pharynx, produces only a trifling inconvenience.

Invasion.—The disease begins from a ca-

tarrh; the person has a common cold, and the latter generally arises from cold and wet. The application of cold only will produce the disease, but it usually results from an union of the two, applied either to the throat or to the feet. A few days after exposure the patient has great hoarseness, and then pain in the larynx takes place. Sometimes it does not arise from a common cold, but, as I have mentioned already, a pretty brisk inflammation of the tonsils takes place, and it spreads from them. Occasionally, too, it takes place suddenly; but I have seen it in the middle of a chronic disease. There is no part of the body which can be inflamed chronically, that may not become the seat of acute inflammation; and therefore this occurrence may take place in the throat. When there is a syphilitic sore throat, or a chronic affection of any kind, patients may suddenly experience great difficulty of breathing, and be in the greatest danger from active acute laryngitis.

Treatment.—Now this is a disease in which, if in any, it is necessary to be most active in treatment. No trifling practice is admissible here; you cannot trust to nature, nor can you trust to medical measures alone—for it is necessary, in many cases which last any time, and which become very severe, to use the combined force of medicine and surgery.

The first thing to be done is, undoubtedly, to bleed freely in the arm—to make the patient faint, if you can—and then to cover the throat with leeches. I am taking it for granted that the patient is able to bear it. The disease may attack a person with syphilitic sore throat, and he may be worn out with mercury and disease, so that you may not be able to bleed in the arm; but still, in most cases, I am satisfied it would be best to set the patient upright, and take as much blood as he can spare—be it three, four, or twenty, or thirty ounces—and produce fainting, if possible. There can be no rule for the quantity; but it may be necessary to take thirty or forty ounces, and apply from six to thirty leeches, according to the age and strength of the patient. After the leeches, a poultice for some time may be a good application; and then, after all, if you please, a blister, but not earlier.

In this disease mercury is recommended by those who do not ascribe any active power to mercury in general. It is of the highest importance to get the mouth tender as early as possible; and therefore you must not wait a couple of days for salivation to take place. You will find in the *Medico-Chirurgical Transactions* a solitary case of the disease recorded where ten grains of mercury were given every two or

three hours till ptyalism was produced; and as soon as the patient began to spit, the affection ceased. I have treated many cases of the disease in this manner, and with the greatest success. In treating a case of this kind, it will not do to give a few grains of calomel night and morning, for the patient is in constant jeopardy, and you are never sure of his life from hour to hour. It would be a good practice to rub in mercury on the extremities. If you exhibit mercury by the mouth, it is necessary to give it in large and repeated doses. I will not say any thing about the dose, because if you know that the patient is soon affected by mercury, a small quantity will do: I only state that it is necessary to get the mouth sore, in one way or other, as soon as you can.

However, if the patient be in great danger, if his attacks of difficulty of breathing come on frequently, it will not be right even to wait for ptyalism; but it will be requisite to make an opening into the throat, so as to enable the patient to live till the mercury produces its effects. Bronchotomy is absolutely necessary in many cases of this disease: by opening the air-passages below the part inflamed, an instantaneous relief is afforded, and the patient will live so much the longer. This cannot have the effect of curing the disease, but it has the effect of enabling the patient to live longer; and, therefore, to live till you adopt other means to cure him. I have had, to speak as a pathologist, some very beautiful cases of this description where the combined force of the two great divisions of the profession have most decidedly saved the patient's life, but where neither would have done alone. A mere opening of the larynx will not cure the inflammation, and the patient may die before the mercury can have any effect; and, therefore, it is necessary constantly to watch the patient; and if the symptoms decidedly grow worse, the operation ought to be performed without delay, because it is an operation which is by no means dangerous; it is one which, if properly performed, can do no harm. The dyspnoea arises, as I have said, from an oedematous state of the rima glottidis; and if you enable the patient to breathe notwithstanding that, as the inflammation subsides the oedema goes down. The paroxysms of difficulty of breathing clearly arise from spasm; and if an opening be made below, so that the patient can breathe through it, the disease may occasion as much spasm as it chooses above, but your patient is safe.

You are aware that the least pressure in these parts will occasion spasmodic difficulty of breathing. In the *Medico-Chirurgical Transactions* you will see a case described by Mr. Lawrence of a person

who had attacks of dyspnœa which arose from the mere pressure of an aneurism of the arteria innominata. The aneurism slightly pressed on the trachea; the pressure was as slight as it could be to be pressure; the direct diminution of the trachea by the tumor was found to be very inconsiderable, but it was sufficient to produce irritation, and to cause violent attacks of spasmodic dyspnœa.

But the inflammation itself, to say nothing of this œdema and tension of the parts—the inflammation of the membrane itself will throw the parts around into a violent spasm, just as you see in inflammation of the urethra and bladder. When inflammation exists about the larynx, the person is continually seized with a violent difficulty of breathing, without any pressure, but merely by the irritation; and many persons, without any inflammation about these parts deserving the name of laryngitis, will die in a moment. I have seen several cases of persons who have been seized with a sudden difficulty of breathing when they were supposed to have only a common sore throat, some of whom have died in the course of three or four hours, and some in a minute. When inflammation exists in the fauces, and extends to the glottis, without descending to the larynx and producing laryngitis, the person may be seized with spasmodic difficulty of breathing, and die instantly. I saw a young man about three years ago who had been frightened in consequence of his mistress pulling him out of bed with a girl at night. This made him nervous, and therefore liable to spasmodic diseases. He merely caught a common sore throat, for which six leeches were applied; and while the ward was full of medical men, a violent spasm seized his throat, and he died instantly. Every thing was done for him that could be, but he was quite dead. I have seen several patients with more decided inflammation than this, but still not deserving the name of laryngitis, who have died in a moment. When, therefore, there is laryngitis, you may well suppose how dangerous the case is, and how necessary it is to be active in the highest degree. Whenever a patient becomes very hoarse, and you hear his voice hissing, sibilous, through the larynx, and find the tube is tender on pressure, alarm should instantly be taken, and the disease treated actively, although the patient may make no particular complaint himself, and although, on looking into the throat, you cannot discover any thing particular.

Formerly called Angina Occulta.—Morgagni and others have described it, proving that it is nothing new to medical men; but from there being no outward and visible sign, in some cases it was called *angina occulta*, to

distinguish it from common sore throat, which they called *angina manifesta*.

CHRONIC LARYNGITIS.

A much more common disease, however, than this is chronic laryngitis, an affection of which you will see many cases.

Symptoms.—This species of the disease is attended by a very hoarse cough, and likewise a hoarseness of the voice; and sometimes the person, both when coughing and talking, appears almost to crow—makes a sort of crowing sound. The alterations in the voice are very great; there is hoarseness, roughness, squeaking, and crowing of the voice, and sometimes it is nearly suppressed. The cough too varies in the same way; sometimes it is very hoarse, and sometimes very shrill. The respiration occasionally in chronic laryngitis is hissing, but not necessarily so; it is observed in most cases, but by no means in all. There is a copious discharge of mucus, and sometimes pus. There is in all these cases, I believe, at least I have always observed it, pain on pressure. If the lungs be sound, you must learn that chiefly by means of auscultation, by listening and finding the sounds of the chest healthy, finding there is no pectoriloquy. However, it is sometimes difficult, when the voice is nearly suppressed, to make up one's mind on the subject. Some say they can tell us as well when the voice is suppressed as when it is not, but I confess I have not attained that perfection.

This disease may occasion great emaciation, and therefore in that respect, as well as on account of the discharge of mucus of a puriform character, patients may easily be supposed to be in a state of pulmonary consumption; and it is a fact that the disease does sometimes co-exist with phthisis pulmonalis.

Morbid Appearances.—After death from this disease we find the common results of chronic inflammation. The mucous membrane is frequently thickened, frequently indurated, frequently it is granulated; it is exceedingly rough, and there are numerous little cavities, if I may so call them; and frequently it is ulcerated. The same appearances very often extend along the trachea.

Treatment.—In the treatment of this chronic form of the disease we are by no means so successful as in the acute—in fact, the treatment for the most part is very unsatisfactory. The best method, however, that you can adopt is, the repeated application of leeches, and subsequently of blisters; the internal exhibition of mercury too is of the greatest use. But if the disease be a scrofulous inflammation, of course mercury will do no good, but rather make things worse. It is best in al-

most all cases to give it a fair trial—taking care not to hurt the constitution, but to make the mouth moderately sore, and keep it so—to treat it as a mere chronic inflammation, and it will very frequently subside, but far more frequently, I believe, the treatment is very unsatisfactory.

It is frequently necessary, on account of the sufferings of the patient, and the harassing cough, to give narcotics—conium answers exceedingly well—to procure sleep. Some have found relief from the inhalation of the fumes of tar, and others from the inhalation of chlorine, either by diffusing it through the apartment of the patient, or making him breathe through water in which a quantity of chlorine exists; but it is very necessary in all these cases not to push the matter to irritation. Tar fumes, chlorine, and many of these things, will produce very great irritation, even in a small quantity; and therefore it is right always to begin by impregnating the water, or the apartment, very moderately, and if it produce no irritation, then you may go on to a great extent.

Some have recommended as a medicine internally, copaiva and eubeds, because they have done good in irritation of another mucous membrane. I have not been satisfied with these, but as they are recommended I mention them. Some have recommended the application of lunar caustic. A solution is made of nitrate of silver, into which a sponge is dipped, and pressed down to the rima glottidis, so as to produce a new action there, and lessen the morbid sensibility, hoping that the same good change may spread downwards which is observed at the very spot at which the nitrate of silver is applied. I have known this remedy employed, and, as you would imagine, fruitlessly; but if the disease were situated merely at the rima glottidis, good would be done by it. I have no experience of it myself, but I have seen cases in which I understood it had been employed without any harm.

APHONIA.

It is right you should be aware that the voice is sometimes lost, or reduced to a mere whisper, without any inflammation—without any oedema—without any obstruction, as it would appear, of the parts; and this occurs chiefly in females, and is altogether what we call a nervous complaint. It occurs sometimes in boys as well as in girls, but it is chiefly an affection of children.

Diagnosis.—I think it is easily made out. There is no tenderness of the larynx on pressure; there are other nervous symptoms in the body, and the person is weak and nervous altogether. Frequently there is no tenderness on pressure, and fre-

quently no cough; or if there be cough, there is nothing but that—no pain with it—no expectoration, and the disease frequently comes on suddenly, and goes off in the same manner. It has frequently come on in the course of a few minutes—at any rate in a day; it ceases perhaps as suddenly, and then comes on again.

Spontaneous Cure.—This is altogether a nervous affection of the part; there is no danger whatever, but sometimes a person loses his voice for many months, and I have heard of cases where they have lost it for years, and from a sudden circumstance, without any apparent reason, the voice will return.

Treatment.—I do not know any mode of treatment better than the shower-bath, and attending to the improvement of the general health in every way you can.

OBSERVATIONS ON DIARRHŒA;

BEING THE

Substance of a Report,

Communicated to the Army Medical Board,

By J. MACLACHLAN, M.D.

Assistant-Surgeon.

Bowel Complaints.

If numbers can attach importance to any particular class of disorders, these were by far the most important which presented in the Reserve during the year. But independent of this, the prevailing epidemic added greatly to their interest, and demanded for them a more than usual share of attention.

On the arrival of the Reserve at Perth, on the 7th April, we found that cholera had been prevalent exactly a month. The disease was then at its height. The number of cases, however, was small, averaging three or four daily, and it was confined to the most wretched characters of the town—the abandoned, the dissolute, and the ill-fed and ill-clothed. So far as I could learn, the Reserves of the Royal and the 71st Regiments, whom we relieved, had not suffered from any complaint connected with the existing epidemic, if we except an occasional case of common diarrhœa; but, conformably to the instructions previously issued from the Horse Guards to the troops stationed in infected districts, as soon as the Reserve of the 79th had marched into barracks, all communica-

tion with the town was forbidden, and until the 24th of September, with few exceptions, the order was strictly carried into effect. In the first month spent in this quarter, more men were admitted into hospital than in any other similar period throughout the year; yet the greater proportion suffered from the usual consequences of a march performed on hard dry roads. There were a few with sickness, giddiness, and headache, and two had diarrhœa, but these might have been easily accounted for without reference to the prevailing disease.

Throughout the whole year cases of diarrhœa were occasionally occurring; but the months of September and October were, in this respect, peculiarly conspicuous. In these months the complaint prevailed to a great extent in barracks. Amongst the men alone, there were twenty-one cases in the first, and nineteen in the second month*. The officers, women, and children, also suffered considerably, so that in that period altogether about sixty cases presented. Cholera spasmodica was still prevailing in the town and neighbourhood of the barracks, although not now officially announced; and by this time, I have good reason to believe, had attacked about 250 individuals. Diarrhœa had all along been common with the inhabitants, and in September and October there was a slight increase, but not at all proportionably to the number attacked in barracks, a circumstance which I was disposed at the time to attribute to their locality; but the probability is, that its greater prevalence with us was more apparent than real, many cases having come before me that would have escaped notice with the civil population, either from their slight nature, or from not being so carefully sought after. I have little doubt, however, that a few cases did originate in exposure to wet and cold while the Reserve was employed at a fire in town; and this opinion is strengthened by the fact, that the company which was longest employed there was that which had the greatest number of cases.

The complaint presented itself in three forms. In the first, the evacuations consisted of the natural contents of the bowels, more or less tinged with bile. This was by far the most common, and out of all proportion to the others. In

the second they were serous, generally scanty in a few hours, and sometimes mixed with feculent matter. The third form was marked by the evacuations resembling cold thin water-gruel, approaching in appearance the characteristic dejections of malignant cholera. In whichever form, there was usually little or no griping; the pulse was occasionally affected; but, very generally, any change in it was confined to the two last varieties; thirst was a frequent accompaniment. Not above five or six cases of the third form were observed. In these there were more or less acceleration of the pulse, dizziness, nausea, thirst; and in two, shooting pains in the lower limbs, without cramp. There were neglected cases in which the purging had existed twelve, eighteen, or twenty-four hours; and, indeed, the second and third forms almost always appeared to me the consequence of a continued looseness: when early application was made, the stools were almost invariably feculent. Frequently, however, if not soon checked, they assumed a pale, watery, or serous character.

In the treatment I was entirely guided by circumstances. If the purging was frequent, and had lasted for several hours, I considered it incumbent to allay the consequent irritation in the first instance, as far as practicable, with opium or hyosciamus, either alone or in combination, with calomel and ipecacuan. When the stools were feculent, I generally gave fifteen grains of rhubarb, with five of calomel and five of ginger, immediately on presentation. The patient was invariably, in all cases, put to bed, and covered with warm blankets. After the medicine had ceased operating, say towards evening, a scruple of the *polv. cret. comp. c. opio*, mixed up in mucilage, with a drop or two of the *oleum menthæ*, was ordered. Sometimes, and not unfrequently, but particularly when the looseness was accompanied by constitutional disturbance, or symptoms of gastric irritation, calomel and opium were employed instead. About three grains of the former to one of the latter was the usual dose; but, more generally, the same quantity of calomel was washed down with twenty-five or thirty drops of laudanum. If, on presentation, the evacuations were serous, the astringents mentioned were immediately resorted to. The patient had already suffered considerably, and every hour increased the danger to be appre-

* The strength of the Reserve at this period was 240.

hended from a continuance of the purging. The object was to check the looseness with the least possible delay; and when medicines by the mouth failed, opiate enemata were substituted or added to them. In the third variety noticed, in which the dejections resembled those of spasmodic cholera, and in which the accompanying symptoms appeared to be premonitory of this formidable disease, blood-letting was seldom omitted. As a precautionary measure, it was now and then had recourse to in other cases, and invariably where the pulse was much accelerated. Ten or twelve ounces was the usual quantity taken. At present I do not recollect an instance in which a second bleeding was considered necessary. When the diarrhoea was attended by sickness and inclination to vomit, with or without quickness of the pulse, an emetic of ipecacuan was generally the first thing given, always excepting cases in which there was *tenderness* at the scrob. cordis. This, followed by the calomel and laudanum in the dose above-mentioned, usually procured free perspiration and sleep, on awaking from which the patient was agreeably surprised to find that the nausea had left him, and the headache or dizziness, frequently accompanying the derangement of the stomach, if it had not also disappeared, had greatly abated. The subsequent part of the treatment in these cases had nothing peculiar. The period which usually elapsed from admission to the day of discharge seldom extended above five or six days—very generally it was less; but in a few cases ten days had been passed in hospital before the diarrhoea ceased, and, in a recent instance, the patient was fully a fortnight under treatment. In all tedious cases, the sulphate of copper, in small doses, dissolved in the emulsion camphore, with the addition of laudanum, was found of essential service.

D. MACLACHLAN, M.D.

Assistant Surgeon 79th Regiment.

CASES OF EYE DISEASES; WITH REMARKS.

By WM. MACKENZIE,

Lecturer on the Eye in the University of Glasgow.

Xeroma Conjunctiva.

AGNES M'KINNON, aged 26, applied at the Glasgow Eye Infirmary, on the

26th March, 1833, under the following circumstances:—

Both conjunctivæ are red, and have evidently suffered from long-continued inflammation. The right conjunctiva especially is of a dark-red colour, and, where it passes from the lower eyelid to the eyeball, of an olive hue, from the frequent use of nitras argenti in solution.

The left conjunctiva has the appearance as if it were skinned over, being in many places of a whitish colour, and, on the inside of the upper lid, looks as if it had suffered cicatrization. It is altogether drier than natural, and seems almost destitute of its proper mucous secretion. The patient says that this eye waters much less than the right. At the nasal extremity of the left lower lid, there is a tendency to symblepharon; the conjunctiva, when the patient turns the eye upwards and outwards, forming a frenum, which prevents the free motion of the eye. There is slight inversion of the left lids, with some inverted eyelashes rubbing on the surface of the eyeball. Numerous red vessels are observed winding over the left cornea.

She says that she has been subject to attacks of ophthalmia for eight years; the first attack being in the left eye, in consequence of a stroke with a shuttle. The conjunctivæ were never scarified, nor rubbed with solid caustic; and she never had any operation performed for the inverted state of lids, except pulling out of the faulty eyelashes. Tongue clean; bowels regular.

The inverted eyelashes were removed, and she was ordered to bathe the eyes thrice a day with a tepid solution of ten grains of murias ammoniac and twenty of gum arabic, in eight ounces of water.

The above is an example of a very peculiar state of the conjunctiva, the result of long-continued and ill-treated inflammation of that membrane. It has been described by Mr. Travers, under the name of *cuticular conjunctiva*. He mentions*, that he had seen cases of this conversion of the conjunctiva into a rugous and opaque skin, go the length of knitting the lids close to the globe, and obliterating the sinus palpebrales. While he places it among the sequelæ of chronic inflammation of the conjunctiva, he considers it as immediately depending on an obliteration of the la-

* Synopsis of the Diseases of the Eye, p. 120. Lond. 1820.

chrymal ducts; a view of the subject which had been taken long before by Schmidt, of Vienna*, who describes the disease under the name of *Xerophthalmos*.

The most recent, and hitherto the most complete, account of this diseased state of the conjunctiva, we owe to Dr. Ammon, of Dresden, one of the most original and ingenious ophthalmological inquirers of the present day†. He acknowledges, however, that the first case of the disease which he had an opportunity of examining, was pointed out to his attention by Professor Jäger, of Erlangen; who, in one of his Clinical Reports, had spoken of this affection of the eye under the name of *Ueberhäutung der Conjunctiva*.

The principal symptoms of *xeroma conjunctivæ* may be gathered from the case of M'Kinnon, as above related. I may add, however, a few remarks; embodying what seems most interesting in Dr. Ammon's paper.

1. *Symptoms*.—Although, in general, the conjunctiva presents a dark-red colour, and has a thickened, rugous, and dusky appearance, it is sometimes whiter and less vascular than natural. It is always drier than in the healthy state, and looks as if it were skinned over. The caruncula has a dry, smooth, flat appearance, is sometimes whiter than natural, and is often scarcely recognizable. The puncta are generally contracted, or closed; sometimes, however, dilated and paralysed. The cornea is dull and nebulous, with red vessels running through its conjunctiva. There is generally a considerable degree of entropium, with trichiasis, fræna approaching to symblepharon, and not unfrequently the conjunctiva is observed to fall into folds around, and especially above, the cornea. If the conjunctiva is touched with the finger, it betrays scarcely any sensibility. When cold or warm water is dropped upon the eye, no sensation seems to be produced. The patient complains of a feeling of dryness, and sometimes of sandiness in the eye. If he tries to weep, no tears flow, but the effort makes the eye red and painful, while no such effect is produced on the sound eye.

2. *Causes*.—Long-continued inflammation of the conjunctiva always pre-

cedes xeroma; and in the course of that inflammation it seems indubitable, both from the aspect of the membrane and the other symptoms, that the secretory structure of the conjunctiva is altered, and its power of forming mucus thereby partially or entirely lost. The kind of inflammation most apt to lead to this change in the conjunctiva, is the strumocatarhal; but it may also follow any chronic conjunctivitis—strumous, catarrhal, or contagious. Dr. Ammon suggests, that granular conjunctiva subsiding, is apt to leave the conjunctiva disposed to fall into xeroma. I am inclined to think, however, that the most frequent origin of this disorganized state of the conjunctiva is either a totally neglected strumo-catarhal ophthalmia, or one treated only with stimulants—such as the golden ointment, the black ointment, and the like. Instead of abating the inflammation by proper soothing and emollient applications, and by the local detraction of blood, it has unfortunately become a too common practice to use only stimulants and escharotics, and some of these so strong that they actually destroy the mucous texture of the membrane to which they are applied; an effect which is followed, after some time, by the conversion of the conjunctiva into a mere cuticular covering. I have seen the mucous membrane of the tongue partially changed in the same way, so as to present numerous white, skinny, unalterable patches. Saturnine applications are probably, in many cases, the cause of xeroma; for if the least excoriation exists on the conjunctiva, the lead, precipitated by the muriatic acid which exists in the mucous and lachrymal secretions, instantly fixes on the excoriated spot, rendering it white and dry, and is very rarely removed. Hence liquor plumbi, Goulard water, and the like, are never used in good ophthalmic practice, however slight the affection of the eye. They are still, however, amongst the favourite applications of the vulgar.

Dr. Ammon, finding xeroma often attended by entropium, has come to the conclusion that the operation of removing a fold of skin, for the cure of the latter, may often be the cause of the former; the incision being made too deep, and the consequent inflammation extending to the lachrymal ducts. But it is a sufficient answer to this notion, that we meet (as in M'Kinnon) with

* Krankheiten des Thänenorgans, p. 55. 1803.

† Zeitschrift für die Ophthalmologie, vol. i. p. 65. Dresden, 1830.

this disorganization of the conjunctiva in subjects who never have undergone any such operation, or even in some who have had no inversion of the lids. That the lachrymal ducts are sometimes closed in xeroma, I do not mean to deny; but may not the same chronic, mismanaged inflammation, or the same violent escharotic applications, which close for ever the secreting pores of the conjunctiva, close also the mouths of the lachrymal ducts? Would mere closure of these ducts, with an otherwise healthy conjunctiva, give rise to xeroma? I believe not; and Dr. Ammon seems inclined to the same opinion. It is the mucus of the conjunctiva, and not the tears, which, under ordinary circumstances, keeps the eye moist and the cornea pellucid. The moisture of the eye and the clearness of the cornea are preserved even after the lachrymal gland is extirpated. But let the conjunctiva (as in the disease now under consideration) be deprived of its secreting faculty, not merely does the patient complain of a feeling of dryness in the eye, and move the eye with difficulty, but the membrane looks like the skin on the back of the hand, and the cornea, no longer guarded against the effects of air, dust, and light, becomes opaque.

Treatment.—Cold applications Dr. Ammon found hurtful in this disease. Tepid ones should be used; and let them bear some resemblance, in physical and chemical properties, to the secretion which the eye has lost, and for the recovery of which there is very little hope. If the conjunctiva be very red, local blood-letting will afford considerable relief. The general health is carefully to be attended to; not neglecting the trichiasis, entropium, and other local occasional attendants on this highly-interesting affection of the conjunctiva.

LABOUR CASE,

WITH A PECULIAR PRESENTATION.

To the Editor of the Medical Gazette.

SIR,

A CASE of labour has just occurred to me, which, on account of one of its peculiarities, appears worthy of being placed on record. Should your opinion concur with mine, you will oblige me by publishing it.

On the 2d of April, at half-past nine A.M. Mrs. W. sent for me. She is a healthy, well-made woman, of sanguineous temperament, in her third pregnancy. The dolores presagientes occurred about twelve hours before; the pains at this time were trifling and infrequent, and, as she was not in her chamber, I left her without making an examination. At 4 P.M. I was again sent for. I found the os uteri dilatable, during a pain, to the size of the palm of the hand, and a bag of extremely strong membranes protruding. I could just ascertain, over the pubes, that a part of some extent of surface was presenting; but whether hard and unyielding, as the cranium, or yielding and fleshy, I could not reach to determine. With some difficulty I ruptured the membranes, but even then, during the subsequent uterine contraction, I could not reach so as to determine the presenting part. I therefore questioned her as to her previous and present sensations, so as to elicit, if possible, the position of the fetus; but I learned nothing—"every thing seeming the same as in her two former (natural) labours." I left the chamber, directing her to rise and walk about the room.

In about an hour the contractions had become pretty frequent and strong, and on examination I found the shoulder and hand passed the os uteri, and engaged in the pelvis. I at once introduced my hand, but the immediate effect was to induce violent contraction. This continued, with no interval greater than thirty seconds. I found the child's head reverted, so that the right ear was lying on its abdomen; but by the time I had ascertained this, these parts, *in statu quo*, were engaged in the pelvis, the shoulder being almost in contact with the perineum. The child was alive at this time, for I felt the movement of its limbs, as well as the pulsation of its heart and of the funis. With the utmost efforts that I considered justifiable, I could reach no further than the child's right anterior superior spine of the ilium; neither foot or knee could I feel. My hand was by this time so cramped that I withdrew it into the vagina, endeavouring now merely to prevent the further descent of the child. It might have been half an hour since I first introduced my hand. I now determined on venesection, in the hope of diminishing the violence of the contractions.

The preparation for this caused alteration in position of the patient's attendants, when I found that the woman at her back had been violently pulling an apron which she had passed round the patient's abdomen. I at once removed it, but am inclined to attribute much of the difficulty I met with to this circumstance.

The pulse was full and strong, and face red. When about a pound and a half of blood had flowed from the arm, the character of the pains altered, and, on examining, I found the shoulder and all the ribs of that side born, being able to pass a finger between the perineum and the child's back. Even now the child was quite moveable in the pelvis, and each subsequent pain increased the degree of protrusion. I now requested a gentleman who was with me to tie up the arm, and then slightly assisted the uterine pains, and the third after the bleeding, aided by great voluntary effort, protruded (or rather *projected*) child, legs and feet, funis, placenta and all, into the world, the perineum being quite entire. The child's head maintained the same relative position to its body which I had before ascertained, but its heart and the funis had ceased to beat.

The patient, according to her own calculation, confirmed (by the memory of communicated facts) by her mother, was two days over her nine months. The child, half an hour before its birth, was, I am certain, alive; yet the head and abdomen passed *together* through the pelvis. The child was certainly not large, and the pelvis extremely well made. The uterine contractions, moreover, were violent; had their conditions been otherwise, I conceive (on authority*) that the birth would not have been effected without the dismemberment, or emptying the cavities, of the child. The child was alive even when the shoulder was on the perineum, and consequently when, in all probability, the head and abdomen had passed together the *brim* of the pelvis; and is it certain (notwithstanding the numerous opposing authorities) that the child, if it had continued to live, *could not* have been born in its then position?

Your obedient servant,
GROVE BERRY.

SMALL POX AFTER VACCINATION.

To the Editor of the Medical Gazette.

SIR,

I READ a few days ago, in the *Medical Gazette*, Mr. Greenhow's letter on small-pox after vaccination, and could not help being struck with the truth of the main statement, that small-pox is of more frequent occurrence after vaccination now than formerly; indeed, the fact is so much in accordance with my own observation—though like him I am anxious for the opinion of other medical men—that I cannot, in the meantime, withhold what has already come to my own knowledge on this important subject.

Many of the causes of failure were long ago pointed out by Dr. Jenner; such as taking the virus at an improper period of the vaccination—allowing the lymph to decompose before insertion—and vaccinating where the skin of the patient was in an inflammatory or eruptive condition; and it is much to be lamented, that every one of these sources of error will produce a spurious vesicle, containing lymph, which communicates the same spurious unprotecting disease as often as it is made use of; and it is equally to be deplored, that it displays considerable resemblance to the genuine cow-pox; but, by testing it with pure virus, the genuine vesicle is produced, and goes through its regular course. In corroboration of the soundness of Dr. Jenner's ideas at that time upon this subject, I can state three cases exactly in point.

In the year 1860, the child of a respectable person of this town was vaccinated by an elderly practitioner, with matter from what he called a well-matured pustule. On the fifth or sixth day violent inflammation surrounded the wound, and rapidly extending over the whole body proved fatal in a few days. The two other cases happened in one family. They were also vaccinated by a gentleman who entertained similar notions with respect to the maturity and bland nature of the virus. The wounds inflamed, tumefied, and speedily ulcerated. A week after the vaccination they were both seized with the confluent small-pox, and died on the fifteenth day. These cases happened through a culpable imitation of what was too com-

* See Naegele's *Mechanism of Parturition*, translated by E. Rigby, M.D.

mon in variolous inoculation, viz. taking the matter at a late period of the disease, when the virus had passed the boundary of perfection with respect to its specific qualities, though capable of acting in the first case as an animal poison, and in the two last as a severe local stimulant.

A more correct knowledge of vaccination has, however, long since prevented the recurrence of such flagrant errors. Still the danger of imperfect vaccination, from causes yet undiscovered, seems to exist pretty generally at the present period; and I cannot divest myself of the notion (fanciful or not) that the process of vaccination is not so characteristic in its appearance as it was upon its first introduction. At any rate I have, I think, clearly observed the areola when it has obtained its utmost extent, on the 11th or 12th day, begin first to fade at its outer circle, proceeding inwards towards the vesicle, and thereby not exhibiting the double areola which, if I am not much mistaken, displayed itself much more universally twenty or thirty years ago than at present.

This double areola is evidently produced by the efflorescence fading first where it begun, viz. near the base of the vesicle, and gradually extending outwards, and thus exhibiting a pale sort of halo round the vesicle in the centre, while, at the same time, the outer edge of this halo is itself surrounded by a red zone. I am far from contending that this appearance is never now observed; I only say that it is not so distinctly marked as formerly. Where it does exist, it is a perfect proof of a genuine process of vaccination; and when it does not exist, there is danger of a spurious or imperfect one.

But although the double areola be wanting, the vesicle is still cellular—a structure first discovered by the late Dr. Cappe, of York, and considered a proof of perfection. The vesicle of the cow is also cellular, and contains lymph of a bluish purple colour, which is retained for a few transmissions through the human subject, and then totally vanishes—a fact which I myself witnessed in performing some successful experiments for the discovery of the origin of the cow-pox, in the year 1801.

If one distinctive mark of the disease should so soon withdraw itself, it is not

unreasonable to suppose that others should do the same in process of time.

The different degrees of protecting influence which vaccination has manifested at various times, when brought to the test by the presence of variolous contagion, is in favour of the notion that some important change has taken place in its character. Although I had vaccinated some thousands since the year 1801, numbers of whom had been exposed repeatedly to the contagion of small-pox, I never witnessed a case of modified small-pox until the year 1815, and that was in my own daughter. The disease was ushered in by great disturbance of the whole system, with intense heat of the skin, sickness, and pain in the region of the stomach and loins; a very white tongue, much thirst, and a quick, soft, undulating pulse. These symptoms were soon succeeded by a rash over the whole body, indicating a most severe eruptive fever, but which, fortunately, was suddenly arrested in its progress by the appearance of a few small pearl-like vesicles, which ran their course in a very few days, and died off without pits. For two or three years such cases were not uncommon, but they all occurred in young persons. The rash always preceded the eruption of hard, pellucid, spherical vesicles, which appeared as early on the body and extremities as on the face, and might very properly be called pearl-pox; for they were at once round and hard to the touch, and became dry in a few days, without previous suppuration.

Of late years this disease has put on a different character, or rather has become less modified, the vesicles being indented, requiring more time in filling, attended by more inflammation at the base, and going on to suppuration regularly and successively, from the face to the extremities—with every symptom, in fact, of genuine small-pox. But it is remarkable, that although some hundreds of young persons and children have had the small-pox, either modified or in their genuine form, not a single instance can be adduced of a father or mother, who had been vaccinated many years before, being affected with either one or the other, although exposed to the contagion in every way possible.

I have observed, therefore, in my own practice, for many years, that vaccination afforded uniform protection; and since

then, an influence from vaccination less and less effectual in resisting the contagion of small-pox, but have never yet seen a fatal case of that disease after vaccination.

I am under the necessity of coming to the conclusion, that the vaccine virus has lost part of its virtues, and that to revert to its origin for a fresh supply, is the only remedy.

I am, sir,
Your obedient servant,
J. G. LOY, M.D.

Whitby, April 2, 1833.

FATTY DISCHARGE FROM THE BOWELS.

To the Editor of the Medical Gazette.

SIR,

HAVING lately met with a case of "fatty discharge from the bowels" (as described by Dr. Brown in a recent No. of the *Gazette*.) at the Parochial Infirmary of St. Pancras, to which I am surgeon, I beg leave to enclose to you the short notes I made of it at the time, and also of the post-mortem examination; and if you think them worth communicating, you will by their insertion oblige, sir,

Your obedient servant,
RICHARD D. EASTCOTT.

St. Pancras Parochial Infirmary,
April 3, 1833.

—, a woman æt. 48, was admitted into St. Pancras Infirmary Feb. 5th, 1833. Has been long ill, and now appears to be suffering from organic disease of the liver, of long standing. The woman, I learn, has been a hard spirit-drinker, and altogether of irregular habits. She has a greenish cast of countenance, and is emaciated; complains of considerable pain in the right side and epigastrium; is subject occasionally to severe pain in the bowels; but what is more remarkable, she passes with her stools, which are very bad, and shew a great deficiency of bile, a discharge resembling tallow, or spermaceti, or like a mixture of both, which floats on the surface of the urine in the vessel in considerable quantities. Was treated with hyd. c. creta in small quantities, leeches, and blisters, and sup-

ported with mild nourishment. She died Feb. 17th.

Post-mortem Examination.—February 19th.—Lungs tolerably healthy, but effusion of serum into the cavities of the pleura—altogether about three pints. Liver soft and somewhat large, of a pale yellow colour (the colour of Flanders brick), and its surface spotted with petechiæ. Gall bladder transparent, not in the least degree tinged with bile, but resembled a particularly thin and well-washed bowel; it contained about two ounces of a thin fluid, more like bilious urine than bile. The colon very contracted—a mere rope; on its mucous membrane, which was very pale, and which was examined throughout its whole course, no trace of inflammation presented itself; the contents, except near the rectum, where there was some appearance of fecal matter, was a whitish secretion resembling blanc-mange, and in other parts of it like thick rice-gruel. I saw nothing like the matter which had been previously discharged per anum. An old adhesion existed between the omentum and gall bladder. The pancreas was hardened, and changed in structure, and the pancreatic duct, which was enlarged, contained a number of solid chalky concretions as hard as bone, some about the size of peas, some larger, and resembling in roughness of their surface the "mulberry calculus" of the bladder. The muscles were attenuated and pale; the cellular substance, particularly about the abdomen, anasarous; and about two quarts of serous fluid were contained in the abdominal cavity.

ON THE SECRETION AND USES OF THE BILE.

By B. PHILLIPS, Esq.

A PAPER bearing the above title was lately read before the Royal Society, in which it appears to be the object of the author to establish the three following propositions, viz:—

1. That the principles of the bile pre-exist in the blood, and that the function of the liver is to separate from the blood a certain proportion of this material.

2. That bile may be secreted as well from arterial as from venous blood.

3. That chyle may be formed in the absence of bile.

In support of the first proposition the author adduces the analogy of other secretions, the suppression of which is followed by the appearance in the blood of the peculiar animal product which characterizes that secretion, as has been proved in the case of the urine by Prévost and Dumas, and afterwards by Vauquelin, Serullas, and Magendie. The author has confirmed the conclusion to which these physiologists have arrived, by some experiments of his own, in which, instead of extirpating the kidneys, he contented himself with tying the venal vessels. He relates two cases in which the vena portæ and hepatic artery were tied, and bile was found both in the urine and the blood.

The author, after quoting several authorities in support of his second proposition, that the liver can secrete bile, although the vena portæ be obstructed, relates two experiments which he made on dogs, by tying the vena portæ at the part before it arrives at the transverse fissure of the liver: in both cases that organ continued to secrete bile, though the quantity was small. In another dog, he tied the hepatic artery, with the effect of producing fatal peritonitis, but without any apparent change in the biliary secretion.

The arguments adduced by the author in favour of the opinion that chyle may be formed when no bile is present in the intestine, are derived from the accounts given by various authors, of cases in which the ductus communis had been rendered impervious by the pressure of neighbouring tumors. In confirmation of this result, he made experiments on four dogs, and found chyle in the thoracic duct after he had tied the ductus communis close to the duodenum.

The author concludes, from these and other facts, that the secretion of bile is intended to serve some other purpose than that of contributing to the formation of chyle.

NEW AND SINGULAR VARIETY OF HERMAPHRODISM;

*Being a Paper read before the Royal Academy
of Medicine, Paris,*

By M. BOUILLAUD.

(Abridged from the *Journal Univ. and Hebdom.*)

—

In the course of the last year there was carried into la Pitié a cholera patient of the

name of Valmont, a *widower*, sixty-two years of age, by trade a hatter, and said to be given to dram-drinking. He was in the last stage of cholera when he entered the hospital, and he died on the following day.

I shall omit all that part of the post-mortem examination which only related to the disease of which this person died; the monstrosity which presented itself to us (Dr. Donné was with me), is what I particularly wish to notice.

As we had no suspicion about the sex of Valmont, who was treated as a male while in the wards, it was with no small surprise that, upon opening the abdominal cavity, we found in it a *well-formed uterus*. We then noted the abnormal state of the genital organs, and had those parts of them removed and put in alcohol which we desired to examine subsequently more at leisure, for the cholera was then raging in all its fury.

M. Manec afterwards requested permission to examine the parts. This gentleman's profound anatomical attainments are well known, and to him I am indebted for the following description, as well as for the plate by which the organs are represented.

In the region of the external genital organs there is a penis of middling size, terminated by a well-formed glans, and prepuce, by which it is covered. The opening of the meatus urinarius is, however, not at the summit of the glans, but towards its lower portion. The bursæ are small, but very distinct, and their integuments brownish, wrinkled, and supplied with hair, as in the natural state; they have a raphe dividing them symmetrically, and extending from the prepuce to the anus—the raphe itself being more firm and prominent than is usual in man. The bursæ contain no testicles, nor are there any vestiges of these organs discovered.

The mons veneris is more round and plump than it is commonly found in males, and it is covered with a moderate quantity of long hair, advancing along the penis, as if to conceal the latter. In the pelvis there are two ovaries, similar in their form and structure to those of a girl of fifteen or sixteen years of age. [M. Bouillaud in a note here differs from M. Manec as to the structure of these supposed ovaries, M. B. considering them not as vesicular, but rather fibrous, or as if they consisted of a sort of

intermediate tissue between that of the testicles and the ovaries.] Two fallopian tubes are seen, with their attachments, as in a well-formed woman. The uterus, which seems complete in every respect, holds its usual place between the bladder and the rectum, and opens into a species of vagina, to be described presently. The cavity of the uterus has the arborescent wrinkles which are observed in women who have had no children. The os tincæ projects into the vagina, as in the normal state. The vagina, about two inches long, and of middling compass, presents the rugæ very conspicuously which are peculiar to virgins. Towards the neck of the bladder the canal contracts; and about the membranous portion of the urethra it is converted into a narrow duct, which from below upwards opens into the urethra by a little orifice about two millimetres in diameter, so that the urethra becomes in fact a continuation of the vagina. There is nothing remarkable about the urethra beyond the point of junction; it is exactly that of the male—having even at its origin the appendage of a regularly-formed *prostate*. There are also the *verumontanum*, and the prostatic follicles present, but no trace of openings to the ejaculatory ducts could be found. Beyond the prostate the urethra is destitute of external covering for eight or ten lines. Farther on a spongy tissue, with a bulbous enlargement, becomes connected with the canal, accompanying it to its extremity, where it is lost in forming the glans. All this spongy portion is attached to the corpora cavernosa, which, strong and well-marked as in the male, are strengthened at their root by a muscular apparatus as complete, and perhaps even more efficient than in the male. The bulbo-cavernous muscles, in particular, are very long and thick. Cowper's glands are present also, as in the male sex.

Like the testicles, the vesiculæ seminales, and vasa deferentia, are completely wanting. From the inguinal ring nothing more than a dense cellular cord—a rudiment of the round ligament—proceeds, accompanied by a nervous thread and an artery. The volume of this artery is considerable, and it communicates by large anastomoses with the superficialis perineæ, and the branches of the external pudics. The external female organs are altogether wanting.

With regard to other points connected with the general structure of this extraordinary individual, and perhaps scarcely less striking than those of the genitals, so well described by M. Manec, I may observe that the body of Valmont, very diminutive for a male, presents a degree of plumpness and rotundity which gives it much of the appearance of a female. The hands and feet are small, and more like those of a woman than of a man. The pelvis is shallow, and wider than it would be in a well proportioned man. The face is furnished with a tolerably thick beard, yet its general aspect is effeminate, and, perhaps owing to its equivocal character, rather repulsive. There is an abundant supply of fat lining the pectoral and abdominal cavities. The mammary glands are much developed—too much, indeed, for a man, and yet too little for a well-formed woman; the nipples are of the size usual in healthy females.

Looking to the general conformation and volume of almost all the other parts, we should say that this individual maintains a sort of *juste-milieu* between man and woman. The heart, however, was nearly as robust as that of a man of middle size and strength.

Such were the anomalies of organization which we observed in Valmont. It may readily be conceived, that we were very anxious to procure all the information we could relative to the corresponding functional or physiological anomalies; but, unfortunately, all our endeavours proved fruitless. Inquiry was made where Valmont resided; but there he had only a little room in which he used to sleep on a bundle of straw. He had no relations or friends; nor could any thing be gathered as to his habits of life, his propensities, manners, or intellectual capacity. Would it not seem as if nature had been determined not to satisfy us with the solution of the difficulties suggested by the anatomical inspection—as if she were in some sort ashamed of revealing the mystery of so strange an aberration?

From Valmont's own account, given upon entering the hospital, it appears he was a widower. Thus an individual with the essential organs of a female—though with the external semblance of those of a male—had been placed in the condition of a husband! Having a womb, did he menstruate? or rather, did he exhibit the phenomenon of being affected with hæmaturia regularly once

FIG. 1.

FIG. 1 (bis.)

FIG. 2.

FIG. 3.

a month? But if, as our most famous physiologists have stated, the fact of being endowed with certain parts indicates the exercise of certain functions, why need we waste time in calculating what must have been the conduct of Valmont? We cannot help thinking, however, that this extraordinary being must have found himself curiously circumstanced. Did the passions of the male, or those of the female, predominate? Did they alternately stimulate him? or was he neutralized by the equal influence of each?

It has been said that, *proper uterum solum mulier est id quod est*. How does the maxim hold with respect to Valmont—a reputed man—and a married man?

In a practical point of view, it might be asked, how should we be able to say, from simple inspection of the exterior, that such a person as Valmont was really an hermaphrodite? Have we the means of forming a diagnosis? The problem is no doubt a difficult one, yet even in the absence of further facts, we might probably venture to affirm *à priori*, that where an individual, as in the case just cited, has a penis moderately (*médiocre-ment*) developed, without any trace of testicles either in the scrotum or inguinal regions, and where, considered in other respects, this individual would seem to hold a middle place between male and female—in such a case, I say, one might venture to affirm, that there are in the interior of the body some of those organs peculiar to the female, and constituting in so far an hermaphrodite more or less complete; and our decision would be greatly corroborated, if it could be ascertained that such an individual had, during a certain period of life, a monthly discharge of blood, or menstrual fluid, from the urethra.

In conclusion, the facts contained in this paper will probably remove all doubt as to the existence of *real hermaphrodis-ism*, however *incomplete*. It is now, we should say, no more than fair to admit that individuals of the human race may be found, who partake at once the male and female type in respect to their genital organs, and, with reference to the other organs common to each sex, present a sort of *mezzo termine* between man and woman; a variety of hermaphrodisism which does not seem to have sufficiently fixed the attention of tera-

tologists. Those who deny the existence of all other varieties except that to which they have given the name of pseudo-hermaphrodisism, will charge us, no doubt, with a credulity amounting to superstition, for having, even in Valmont's case, admitted the existence of a particular kind of true hermaphrodisism: but such a charge will affect us little. We must believe that of which we are persuaded, even though it were a miracle: and, perhaps, of all superstitions (if we may be allowed the term in speaking of natural science) that is the most worthless, not which believes what does not exist, but which refuses belief to what really does. To conclude in the language of a learned professor: "In matters like the present, which are at variance with received opinions, it is the part of wisdom not only to refuse acquiescence in what has not been rigorously proved, but not to fix too narrow limits to the powers of nature*."

CICERO.

ON THE

COMMUNICATION BETWEEN THE
MOTHER AND THE FŒTUS.

THE nature of the communication which exists between the mother and fœtus is one which has naturally excited the attention of the anatomist and physiologist, from the earliest periods at which the structure and functions of the body became subjects of investigation: it is one of those inquiries to which some of the most scientific men of the last century devoted a large portion of their time and study: it has lately been renewed by some of our own contemporaries,—but it still remains undetermined. The great name of Hunter, indeed, in its double force of the illustrious brothers, gave weight and currency to certain opinions and alledged discoveries, to which both laid claim; and, in this country at least, their views passed nearly, if not wholly, undisputed for about forty years. Recently, however, the investigations of Dr. Robert Lee, as published in the *Philosophical Transactions*, have led to a fresh consideration of the subject; and although we have refused to open our pages to that which we regard as a mere personal matter—we mean the charge of plagiarism adduced by Dr. Granville against Dr. Lee—we yet look upon the subject, when separated from its controversial adjuncts, as possessed of peculiar interest, while it is one to which we know that the attention of a large portion of our brethren is at present directed. We have therefore taken some trouble to collect and digest the most important doctrines connected with it, in order that we might lay before our readers a full and impartial statement

of all that has been done up to the present time.

The first circumstance which strikes us, is the extraordinary degree of contradiction as to facts—from which necessarily arises an equal discrepancy as to opinions.

The simplest idea, and that originally entertained, was, that a direct communication by inosculation of vessels existed between the mother and child. This seems to have been the opinion of Albinus and Noortwyck, and undoubtedly was that of Fabricius, Cowper, de Vieussens, and Meekel the father, who affirm that injections thrown into the vessels of the uterus might be made to reach the fœtus. Haller appears to have been led, in deference to these authorities, to adopt this view—at least he refers to some of their statements as the grounds of his opinion, though he admits that he himself never could succeed in obtaining the same results. One of the most remarkable instances of this alledged transmission of fluid from the maternal to the fœtal circulation, is that related by the elder Meekel; but it is enough perhaps for us to remark, that his son, who we may naturally suppose was desirous to vindicate his father's claim to so important a discovery, has been led to an opposite conclusion, and states * that the circulating systems of the two are absolutely distinct.

Another argument, indirect, but forcible, if founded on fact, is, that the fœtus may be blanched of its blood by wounds causing profuse hæmorrhage from the mother; and here again the authority of Haller may be adduced, as he refers to instances of this kind in proof of the doctrine that the vessels of the two communicate directly with each other†. It must be confessed, however, that the cases in which pregnant women have perished

* Manuel d'Anatomie, tome iii.

† Haller's Physiology, chap. xxxi. p. 891. Edit. 1786.

from loss of blood, without the fœtus having participated in the depletion, are much more numerous, satisfactory, and precise. Such an instance, indeed, is related by Wrisberg, the learned illustrator of Haller: he says, "I have seen a fœtus whose mother had died in the seventh month of gestation, of a very bloody wound, with great effusion, which, however, had lost no blood out of the heart and large vessels—nay, not even in the placenta itself did the state of the blood-vessels exhibit any marks of hæmorrhage. Next, I have killed pregnant dogs and cats, by cutting the carotids, and seen cows and mares slaughtered by a very large wound of the heart, without finding in any of them either the ova or fœtus shewing the least defect of blood*." De Reuss also describes his examination of the body of a woman who had died of hæmorrhage, in which the vessels of the uterus were absolutely empty, while those of the placenta, chord, and fœtus, were well filled†.

The inability experienced by all who have recently tried it, of making injections pass from the mother into the child, and the negative evidence of such facts as the preceding, led to the conclusion that no direct communication existed; nor did the inference rest here; for it was maintained by some, not only that injections would not pass to the fœtus, but that they did not reach the placenta—or at least not without rupture of vessels. Indeed Rœderer, so early as 1759, distinctly states, that a large quantity of wax may be found in the placenta when injections are performed from the maternal side, but that this arises from the thin parietes of the uterine vessels being driven against the surface of the placenta and lacerated‡. Wrisberg also, in his notes to Haller,

says, that even by the most successful injections, conducted with every care, he never could throw the smallest quantity of the subtlest fluid into the uterus from the vessels of the chord, nor from the vessels of the uterus into the placenta; the injection entered only the cellular texture of the "fungous chorion." This experiment he tried once on the body of a woman who had died of a wound in the seventh month of utero-gestation, and several times on some of the lower animals. The more general opinion, however, certainly was, that though there might be no direct inosculation of vessels, there was yet a blending of substance—a collocation, as it were, of surface between the mother and child, through the medium of the placenta, by means of which some change was effected on the fœtal blood—if, indeed, a positive supply of nourishment were not supplied by absorption, or otherwise.

The theory advanced by the two Hunters, it were, of course, superfluous to describe: suffice it to say, that while William speaks of the blood from the uterus passing by the arteries into "cells," from which it is returned by the veins*, John compares the arrangement of the parts to that of the "cavernous" substance of the penis†. This explanation seemed to remove the perplexities which had previously existed; it had an air of probability, from its analogy to the mechanism of respiration, in which the air represents the maternal blood entering into vesicles, and the dark current sent into the lungs from the right ventricle, the blood of the fœtus, transmitted to the placenta, to be arterialized. The difficulty of the investigation, then, the plausibility of the theory, and the authority of the Hunters, led to their view of the sub-

* De Structura Ovi. et secundarum.

ject being very generally received and admitted in all the schools of this country, if not of Europe, as the orthodox creed. In the edition of Meckel's Anatomy, published in 1825, by Jourdan and Breschet, the idea of the Hunters is adopted in its fullest extent, and delivered, not as matter of opinion, but as matter of fact. The passage from arteries to veins is said to take place in the uterine placenta, not by anastomoses, "but through the medium of large cells, which may be completely filled either from the arterial or venous trunks*." We think, therefore, that although some individuals may be found who called in question the Hunterian doctrine, yet their objections had attracted comparatively but little notice, and that, upon the whole, the existence of some intermediate cavity, into which the blood of the mother was poured out from the open mouths of the vessels, was as generally received as any doctrine in physiology.

The writer, however, who about this period devoted his attention most assiduously to the subject, was Lobstein; a distinguished physiologist who still continues to fill the chair of midwifery at Strasburgh. He specifically denies the existence of cells in the placenta: there is, he says, no other cellular substance in it, nor any other cavity, besides that which belongs to the venous sinuses, and there are no intervals but those formed by the separation of the vessels which constitute it†. Nevertheless, he holds that the uterine vessels pass into the placenta, and that this is composed of two sets—arteries and veins—one maternal, the other fetal; and that it has sinuses into which the uterine blood is admitted‡.

Ruyseh also denied the existence of

cells*. But the absence of direct communication, by blood-vessels, between the maternal and fetal vessels, while yet the former were held to enter the placenta, led to the conjecture that absorption took place for the nourishment of the child. The Hunterian doctrine seems, however, to have gone somewhat farther in this respect, and to have supposed yet another set of vessels, provided with valves, which absorbed the maternal blood and transmitted it to the umbilical veins. Reuss also speaks of certain vessels with valves, which he supposed to act as absorbents. Schreger, in 1799, dwelt more minutely on these vessels, which he maintained to be genuine lymphatics: and this view, which was adopted by several, has more recently been taken up by M. Lauth, who has written a paper, the chief object of which is to prove that the communication between the uterine and fetal system is effected by lymphatics; though it is remarkable that he makes no allusion to his predecessor, who had maintained precisely the same doctrine; nor, indeed, to any other authority whatever.

Nothing, perhaps, is calculated to convey a stronger impression with regard to the imperfection of our knowledge as to the anatomical facts, and to the difficulty that exists in judging between controversialists, than the statements of anatomists with regard to these same lymphatics. Schreger asserts their existence—Lauth assumes it—Fohman depicts them, and Mayo gives him credit for his accuracy. "Lymphatics (says he) there are in plenty, both in the placenta and the cord†". On the other hand, Lobstein expressly asserts, that, after the most careful research, he never could find them‡. Bichat affirms that their existence has

‡ Page 77.

never been demonstrated, and is "purely gratuitous;" while Meckel says, *totidem verbis*, "there are no lymphatics in the placenta*:" and Weber†, the most recent, and not the least distinguished of the continental writers on this subject, denies the assumption of Schreger, and questions the fidelity of Fohman.* When so much contradiction exists among anatomists, as to what we are to receive as facts, it cannot be wondered at that this should ever have been a fertile source of dispute as to matters of opinion.

It may be proper here to observe, that white, dense, tendinous-looking threads, were described by Wrisberg as existing chiefly on the chorion, where it covers the fœtal surface of the placenta; and as penetrating the substance of the part accompanying the vessels, but easily distinguished from them by their whiteness and greater density. They were minutely described by Lobstein, more than thirty years ago; who found that some of them were more or less pervious, and that they became more numerous in proportion to the advancement of the gestation. These filaments he held to be obliterated blood-vessels, no longer required, and increasing in number as the time of complete separation between the mother and fetus drew near. This explanation of the appearance is referred to, and admitted as correct, in Roux's edition of Bichat‡.

But the question, as to the existence or non-existence of lymphatics in the placenta, is by no means the only one with respect to which anatomists are at variance. One would, *à priori*, suppose it a point admitting of easy decision, whether, on throwing injections into the uterine arteries, they could or could not be made to reach the placenta. Some of the earlier anatomists, as we have seen, maintained that

they reached not the placenta only, but the child itself. This position, however, being now abandoned, there yet remain two opposite statements to be dealt with: one set of experimentalists asserting that injections do pass into the natural uninjured structure of the placenta; others, again, alledging that, where injection from the maternal side reaches so far, it does so in consequence of the vessels being ruptured. This last is no new idea, but it is to be found so early as the papers of Rœderer and Dr. Donald Munro. It has been adduced by others at different times, and, to take the two latest authorities, has been recently mentioned by Lauth, as preliminary to what he says of the lymphatics, and more specifically insisted upon by Lee. Most of those who have adopted this view have described the injections as escaping between the uterus and placenta; and although Lauth be a mere copyist, and says no more on this point than had previously been done by others, yet, as his opinions have of late been particularly referred to, we shall quote his words.

"As to the cells which are described between the uterus and placenta, or in the uterine portion of the latter where the arteries terminate, and veins commence in order to absorb the blood which is there poured out—I never could discover them, notwithstanding the attention with which my researches have been conducted. Perhaps it is the effusions sometimes formed between the two organs, by the substance used for injection, which has led to the admission of their existence; but these effusions depend on the displacement of the placenta and the decidua, and on the rupture of the vessels which unite it to the uterus, and they sometimes take place to so great an extent, that the placenta only remains attached at the edges. Perhaps also the blood-vessels, when much dilated—as is seen in all organs the vital properties of which are over-

excited—may have been mistaken for cells*.”

In order to support his opinion, Dr. Lee, of course, found it necessary to disprove, if possible, the accuracy of the Hunters—examining a preparation in the College of Surgeons, supposed to have been made by Mr. John Hunter, and getting Dr. Nimmo to institute a similar scrutiny regarding those of his brother, in the museum at Glasgow. In the former instance Dr. Lee found flattened portions of wax between the uterus and placenta, “where the injection had lacerated the deciduous membrane, and formed deposits in the vascular part of the placenta.” With respect to the preparations in Scotland, the inferences drawn by Dr. Nimmo, and confirmed by Mr. Broughton, are very much in favour of Dr. Lee: but it is proper to add, that those of Professor Burns are not less favourable to the doctrine of the Hunters†.

But admitting that, in certain cases, the subtlest fluids, including air, have failed to reach the placenta, when thrown into the maternal arteries, and that in other instances wax and similar matters have found their way into the structure of the placenta by extravasation, it will

still be necessary to place in the opposite scale the positive statements of numerous anatomists of repute, who have described experiments performed by themselves and others, in which injections have passed from the hypogastric and spermatic arteries into the placenta; in which they describe its distribution without attributing its presence there to extravasation—a phenomenon which skilful and practised observers could scarcely have overlooked. Passing by the authority of the Hunters, and the more recent statements of various others, particularly Professor Burns, we shall confine ourselves at present to what has been adduced by Von Baer. This anatomist describes the arrangement in different classes of animals, shewing that in some there is an entire separation of the maternal and foetal portions of the placenta; that in others they are merely applied to each other—indented, but without adhering; that in others (including the human female) they become not merely in juxtaposition, but intimately intermingled; and that the vessels from the uterus, on the one hand, and from the foetus, on the other, pass over each other; so that the maternal vessels spread them-

* Lauth's paper has recently appeared in an English garb, and we must say that much more originality is displayed in the translation than in the essay itself; as a specimen, we subjoin the passage above quoted, by which the reader will see how foreign articles may be *done* into the vernacular. We request attention to the passages which we have placed in italics.—ED. GAZ.

Lauth's French.

Quant aux cellules qu'on décrit entre l'utérus et le placenta, ou dans la portion utérine de ce dernier, ou viennent se terminer les artères, et où naissent des veins pour y absorber le sang qui y est épanché, j'en ai jamais pu les découvrir, malgré l'attention avec laquelle j'ai dirigé mes recherches. Ce qui a pu donner lieu à en admettre l'existence, ce sont les épanchemens que forme quelquefois la matière à injection entre les deux organes: mais ces épanchemens dépendent du décollement du placenta et de la membrane caduque, et de la rupture des vaisseaux qui l'unissent à l'utérus, et ils sont souvent étendus au point que le placenta n'y adhère plus que par ses bords. Peut-être a-t-on aussi pris pour des cellules des vaisseaux sanguins très dilatés, comme on en remarque dans tous les organes dont les propriétés vitales sont sur-excitées.

Lancel's Translation.

As to the cells that have been described as existing between the uterus and the placenta, or in the uterine portion of the latter where the arteries are about to terminate, and the veins to commence to absorb the blood which is effused, I have never been able to discover them, notwithstanding the care with which I directed my examinations [for that purpose]. To admit that they can give origin, is to allow of their existence. These are the effusions which the injected matter sometimes forms between the two organs. But these effusions depend on the separating of the placenta from the WEAK membrane, and on the rupture of the vessels which unite it to the uterus, and they are often extended to the point where the placenta does not adhere excepting by its extremities. Perhaps they are also taken from cells of bloodvessels very much dilated, as we observe in all organs in which the vital properties are over-excited.

† For original correspondence on this subject, see Medical Gazette, vol. x.

selves on that part of the fetal placenta which is directly attached to the chorion, while those from the child ramify on the part which lies next the uterus, without the two sets communicating together*.

This, which is described as the result of actual examination, and by injections in different classes of animals, corresponds with what was witnessed in a case of recent occurrence, at the Middlesex Hospital. A nurse having died in the last month of pregnancy, leave was obtained to inject the uterus. Size, coloured red, was first thrown into the vessels of the mother, and on opening the uterus the surface of the placenta next the foetus exhibited the injection in striking display. The umbilical vessels were next injected with size coloured yellow, and on afterwards making a perpendicular section of the placenta, the yellow fluid was found in many places to have run in among and passed the red size, and to be very distinct towards the uterine aspect—the appearance being regarded by several competent judges who were present as not dependent upon extravasation;—certainly there was none between the uterus and decidua. Another remarkable appearance was, that, on removing the placenta, there remained projecting from the uterus portions of size broken across, and conveying the idea of their being the trunks of vessels which had penetrated the placenta. Burdach, we may here observe, states, in the second volume of his Physiology, that at an early period the maternal part of the placenta is but loosely connected with the fetal; so that it may be separated from the latter by maceration.

Of all the descriptions, however, which we have met with in the course of our researches, that by Professor Weber, in his edition of Hildebrandt's Anatomy published last year, is both the most recent, and to us the most satisfac-

tory. We shall therefore here introduce a condensed extract from his work,—the rather as the subject has been but superficially handled in some of the systems of anatomy lately published in this country.

The *decidua vera* lines the whole inner surface of the uterus, and is provided with proportionally large and numerous blood-vessels, which penetrate it in a very oblique direction from the inner surface of the uterus. These vessels do not possess the same number of coats as arteries and veins elsewhere; they have only the internal coat in common.

The *decidua reflexa* is not formed, as Bojanus and Velpeau suppose, by the ovum as it descends from the Fallopian tube, pushing the shut sac of the decidua vera before it, but, as William Hunter stated, the ovum passes fairly into the cavity of the decidua vera, and then the decidua reflexa, so called, is formed by effusion of lymph. W. Hunter represented that there were three openings in the decidua vera, by which the Fallopian tubes and neck of the uterus communicated with its cavity. Carus confirmed the statement of Hunter. Bojanus, Velpeau, Breschet, and Heusinger, assert that the decidua vera and reflexa form together a shut sac, in which, at a certain period, a fluid is contained. Wagner* believes that both cases occur—viz. that in which the decidua forms a shut sac, without prolongations into the neck of the uterus or Fallopian tubes, and that in which there are apertures below and at one or both Fallopian tubes. Lesauvage, also†, found it open, both at the cervix uteri and Fallopian tubes.

Chorion.—The upper part (in the ordinary situation of the ovum) of this membrane, contributes to the formation of the placenta, and is distinguished by a number of long, thick, closely-set, arborescent flocculi and villi, which project from its convex surface, and are sunk into that part of the decidua which forms the uterine or maternal part of the placenta, and whose innumerable delicate extremities are as fine, and even finer, than hair. The flocculi are at first, in very young embryos, without blood-vessels, and are composed of a transparent substance covered by a

* Untersuchungen über die Gefässverbindung zwischen Mutter und Frucht. Leipsic, 1828.

* Meckel's Archives, 1830, p. 100.

† Magendie's Journal, 1831, p. 131.

sheath or prolongation of chorion. At this period the villi are here and there swollen, not regularly cylindrical, and very frequently distended in a vesicular form at their extremities. At a later period there are developed in these villi arteries and veins, which are prolongations of the umbilical arteries and veins of the fœtus. The villi (zotten), as well as the blood-vessels in them, divide in an arborescent form, but the adjoining villi or blood-vessels never inosculate or unite to form one villus or blood-vessel. At the hair-like extremities of the villi there is an evident termination of the umbilical arteries in the umbilical veins, as I have distinctly proved in examining with the microscope villi which I had injected. The blood-vessels never form a network; in the trunks of the arborescent villi there is generally but one artery and vein, which when the villus separates into branches likewise subdivides, so that in the smallest branches of the villi these two vessels are found lying together. At the round extremity of the villi the two vessels meet, and terminate by an arch in each other, forming a loop. These vascular loops do not completely occupy the villi, for at the sides, and in the loop, are seen transparent spaces. In the whole of this distribution, even in the largest branches, the umbilical vessels are transparent; they do not present a coat corresponding to the cellular one of the arteries and veins elsewhere; the middle yellowish fibrous coat of the arteries is wholly wanting; and even by the finest injections no vasa vasorum are observed in them.

The *Placenta* is the highly vascular conjoined part of the chorion and the tunica decidua vera. A uterine and a fetal part are distinguishable in it.

The *uterine* portion is that part of the decidua vera to which the flocculi of the fetal part do not reach, into which, however, very numerous and large arteries, and still larger veins, pass in a very oblique direction from the inner surface of the uterus. These blood-vessels do not possess, as has been already stated, all the coats which belong to arteries and veins elsewhere. They have only the inner coat in common, and are therefore, as the substance of which their sides are formed is very soft, and like coagulable lymph, easily lacerated. The veins form a network, communicating freely with each other, and have this peculiarity—that they enlarge the

deeper they penetrate between the cotyledons of the fetal part of the placenta. The larger veins, where they penetrate into the maternal part of the placenta from the uterus, are the size of a goose-quill; the larger arteries are about that of a pigeon's quill.

The *fœtal* part of the placenta (of course in woman) consists of the numerous arborescent flocculi of the chorion which project into the wide venous canals, which, proceeding from the inner surface of the uterus through the decidua vera, penetrate between the flocculi of the fetal part of the placenta, and there form a network. The fetal part of the placenta is divided into numerous cotyledons. To each of these a large branch of the umbilical arteries and veins proceeds, and subdivides. These cotyledons are covered and held together on their uterine aspect by the maternal part of the placenta. Hence it will be perceived, that, from each surface of the placenta, arteries and veins proceed into its interior, and there come, or are brought in a very singular manner, into intimate contact.

We may convince ourselves that the above is the real structure of the placenta, in the following way. Let a pregnant uterus be opened and washed, and then placed in spirit. When it is somewhat hardened, let one of the large veins in its substance be opened, and then air blown into it; when we shall find that this passes, amongst others, into the veins which run from the uterus into the substance of the placenta. If we then open these with a pair of scissors, we may satisfy ourselves that they are veins, from the smooth surface of their cavities, from the way in which they give off or receive branches, and from their continuity with other veins. We find that their coats are very delicate, and only consist of the extremely thin, smooth internal coat and surrounding coagulable lymph.

Proceeding carefully with our inflation and division, we come to canals which no longer look like veins, but like spaces and passages between the villi of the fetal part of the placenta. Sometimes we are so fortunate as to come to a place where we perceive the manner in which the veins are connected with the villi—viz. we find, at the edge of the placenta, sometimes in it, veins into whose cavities here and there a small villus of the fetal part of the placenta projects, whilst, in other respects, they

present all the characters of distinct internally smooth canals. At such places we can satisfy ourselves that the foetal villi do not project into the veins through apertures in their parietes, but that the internal, extremely delicate, coat of the vein is here projected inwards, and forms a covering to each floeculus or fringe.

At most places of the internal part of the placenta, where the veins and the floeculi projecting into them are large and numerous, they do not resemble veins, but appear like spaces between the floeculi and trunks of the floeculi; which spaces present a smooth surface, and are not occupied by cellular texture.

As it is certain that the blood-vessels of the villi of the foetal part of the placenta have no open extremities, but terminate in the form of a loop in the umbilical vein, the circulation of the blood in the child is so separated from that of the mother in the placenta, that in the natural state a passage of blood from the one class of vessels into the other is not possible*.

Absorbents. — Mascagni, Cruickshank, Wrisberg, and lately Fohman, have supposed that they had discovered absorbents in the placenta or umbilical cord, and Sehreger even endeavours to assign causes why they should exist; but these observations and reasonings are insufficient, and probably founded in error.

Before we conclude, we must briefly advert to an opinion of Dr. Lee, which we believe to be original;—namely, the structure which the veins on the surface of the uterus display. That they present orifices which are usually found patulous, has long been known. They were described, and even delineated, by Rœderer, who, however, regarded them not as natural openings, but as the effect of laceration—an opinion in which Burdach coincides. John Hunter says, that the veins of the uterus which bring back the blood from the placenta, begin on its spongy substance “by such wide openings as are more than equal to the size of the veins themselves;” and Cuvier tells us, that “many of the large

branches of veins pierce the internal membrane of the uterus, and exhibit oblique apertures in its cavity; these (he adds) are true venous sinuses, into which the cotyledons of the placenta insinuate themselves.” The existence, therefore, of such openings may be regarded as having been the doctrine of the highest authorities on this point. Dr. Lee, however, has given a different view of the subject, representing the alleged apertures as naturally existing in the sides of the veins, and as being brought into view on the separation of the decidua; and this idea seems to be supported by the examinations of the parts under water, made by Mr. Owen.

It is impossible for any one who sits down to the investigation of this subject with an impartial mind, not to be struck with the contradictions which exist in the works of the most esteemed writers, and consequently with the difficulty of knowing exactly what to receive and what to reject. Much of this obscurity, we are inclined to think, has resulted from the parts having been examined at different periods of utero-gestation, and the appearances then discovered having been assumed as applying to all other instances. That the opportunities of examining cases calculated to elucidate this subject which any individual is likely to enjoy are not numerous, except at the full period of pregnancy, is quite obvious, and we suspect that observers have generalized too much on solitary facts—but particularly, that what phenomena are seen at a near completion of the process, have been prematurely held to apply equally to the earlier stages of gestation. The appearance of some of the parts differs so much at different periods, that an essential change must necessarily take place in their structure; for example, the maternal part of the placenta is stated by Burdach to attain, in the fourth and fifth month, “a thickness of about four

* Hildebrandt's *Anatomie des Menschen*. 4th edition; edited by E. H. Weber, Professor of Anatomy at Leipsic. Vol. iv. Brunswick, 1832.

lines;" but at the end of pregnancy it is only "an inconsiderable thin layer*."

The phenomena presented by injections, and other modes of examination, must necessarily be very dissimilar in circumstances so different, and the varying condition of the parts may thus account, in some degree, for the discrepancies which exist both as to facts and opinions. The subject is one which, in this country, has been too much neglected since the time of the Hunters: we therefore consider the profession as under great obligation to Dr. Lee for having rekindled the spirit of inquiry by his interesting papers; and we trust he will continue to display the same zeal, the same independence of authority, and the same determination to examine and judge for himself, which he has hitherto evinced.

EPIDEMIC INFLUENZA.

ABOUT a fortnight ago, a severe form of catarrhal epidemic began to shew itself in London, and has since become extremely prevalent. It usually commences suddenly with headache and feelings of general discomfort, attended or soon followed by cough, hoarseness, or loss of voice—oppression, and sometimes severe pain in the chest—tenderness about the ribs, and sense of having been bruised about the limbs and muscles. For twenty-four or forty-eight hours the constitutional disturbance is sometimes very great—with considerable anxiety, and turbulence of the circulation; but after this time the urgency of the symptoms abate, leaving, however, in some cases, extreme languor, which only slowly subsides. The disease, so far as we have seen, does not particularly affect those who are subject to common catarrh; many certainly have it who are not at all liable to "catch cold." With respect to treatment, the patients do not require, nor bear, the depleting means which the severity of the symptoms under other circumstances would warrant. We presume that it is to be looked upon as the epidemic influenza which has lately prevailed in the eastern parts of Europe, and that it is travelling, like many of its predecessors, to the west.

HOTEL DIEU.

CLINIQUE ON DISEASES OF THE EYE,

By M. SANSON.

AMAUROSIS.

[Concluded from page 32.]

WITH respect to the prognosis of this complaint, when it has arisen from some curable irritation of a part remote from the seat of vision, we may anticipate the consequences to be least serious. When it comes on suddenly, it is considered to be secondary; and even when it is traceable to cerebral congestion, there is chance of cure. But when amaurosis creeps on slowly, our presage must be of the worst description; for all we can hope to do, in this case, is to render the complaint stationary. When neglected for a long time, or suffered to become chronic, it is quite incurable.

It is not enough to distinguish amaurosis from other affections of the eye; we should be able to discriminate the different species of amaurosis. Thus *sthenic* amaurosis is that species which is characterized by symptoms of congestion and irritation of the organ, headache, bright and coloured ocular spectra, and by the rapidity of the disorder. Often, too, in this species the eyes are red and suffused with tears from the commencement; the pupil is almost closed up, and there is a photophobia present more or less intense. When the eye is very transparent, and the complaint proceeds slowly, and the iris is motionless—the pupil dilated, and of a black or dark greenish colour; when the spectra are sombre, and there are no symptoms of irritation experienced; then we should call the amaurosis *asthenic*.

As to the origin of the disease, it is only by reflecting seriously on the circumstances attending its development in each case, that we can determine whether it arises from lesion of the retina, the optic nerves, the brain, or some remote organ.

Treatment.—Of all our remedial measures in this complaint, there are but few that can act directly on the retina, either as stimulants or sedatives: whilst, on the other hand, most of them are adapted for attacking the causes of the affection;—and what can be more desirable than this? *Ablata causa tollitur effectus.* The treatment must, of course, vary according to the different sorts of amaurosis.

In the *idiopathic sthenic* kind we should recommend repose, and covering the eyes with a bandage; first removing any foreign bodies that may have been in them. General bleeding is indicated if the eye be irritated, inflamed, and red: in a minor

state of inflammation, a quantity of leeches to the lower part of the orbit will suffice. The amount of the bleeding must be in proportion to the strength and age of the patient; for, by an excess in this respect, we may deprive ourselves of an energetic means of subduing the disorder. The patient should take foot-baths morning and evening, and be put on a mild and liquid regimen. Our next step towards a cure should be to have recourse to derivatives and revulsives—such as vesicatories and setons to the nape of the neck. Mild purgatives, repeated every other two days, have a good effect in superinducing a counter defluxion from the mucous membrane of the intestines. Calomel and all the mercurials are famous for this.

If there have been no congestion, or that it has been removed, and there now remains only simple photophobia, we may drop into the eyes some liquid laudanum, or extract of belladonna. Storck has praised highly the effects of extract of hemlock, taken internally. Should we have reason to consider this sort of amaurosis as arising from any metastasis induced upon the eye, we should attempt to repel it to its original situation: thus we should re-establish hemorrhoids—suppressed menses; for which purpose, the application of a small number of leeches to the anus, or vulva, or upper and inner part of the thighs, for five or six days, will be found efficacious; for, in place of a defluxion, this mode produces rather an inflammatory congestion, which gives rise to hemorrhoids, or the catamenia. Sudorifics will be found beneficial where the complaint may be traced to suppression of perspiration. Emetics may also be employed, in this case, with good effect. Sternutatories are not without their advantages, when they are taken for an amaurosis occasioned by suppression of a nasal catarrh. Purgatives are suited to reinstate a diarrhoea which may have been hastily suppressed, and thus have caused the disorder.

In the treatment of the *symptomatic sthenic* amaurosis, there is much analogy with that already laid down. Our first care, however, should be, once the cause of the affection has been well ascertained, to act on the brain in the first instance, and then on the eye itself. If there be symptoms of congestion or cerebral affection present, we should have recourse to bleeding, general and local. In the last indication, leeches should be applied behind the ears, then vesicatories about the head, syncipital cauterization, &c.

All these methods should be practised with patience and perseverance; for it is sometimes not till after six or eight months,

a year, or sometimes longer, that a favourable change is effected. This tardiness of cure is one of the most serious difficulties in the treatment; patients can scarcely be induced to submit to it; those in hospital, tired out by long residence, pray for their discharge before any positive amelioration is procured.

Sympathetic sthenic amaurosis is rather a rare form of the disease, for where sympathy is excited in the retina in consequence of some derangement of a remote organ, it is rather of the asthenic than sthenic character. The first care is to be bestowed on the affected organ. If the disturbing cause be a gastritis, or other intestinal complaint, antiphlogistics should be employed; anti-hysterics, if the patient be liable to hysteria; anthelmintics, if the amaurosis can be traced to the presence of intestinal worms in the digestive tube.

In amaurosis which is *directly asthenic*, the treatment is altogether different from that employed in the first or second kind above mentioned. Thus, for example, we should expose the eye to a light gradually more intense. Richter says he succeeded by exposing the eye to the light of the sun. A flash of lightning has in some cases cured an asthenic amaurosis. Direct stimulants are used, such as exciting eye-washes, lotions, douches of medicated waters, electricity, &c. We should try also to stimulate the retina directly, by the application of moxas over the course of the nerves of the fifth pair—to the forehead—the side of the nose, &c. Frictions on the eye-lids with diluted cantharides ointment, are also beneficially practised.

In *symptomatic asthenic* amaurosis the treatment must be varied, and is difficult. If the complaint originates in indirect asthenia of the retina, itself depending upon sthenia of the optic nerve or the brain, then we should employ the remedies indicated for sthenic amaurosis. If, however, the asthenia of the retina results from a sthenic affection of the brain, we should treat the cerebral symptoms first, and then employ the treatment directed for asthenic amaurosis.

As for the *asthenic sympathetic* form of the disease, it is very rare, unless where the patient manifests a general asthenia of the system; and in this case tonics are to be recommended; steel, mineral waters, irritants, &c. are useful. But whatever remedies we employ on remote organs, we should not overlook the more direct treatment which is suited to the organ of vision.

The treatment of the last form is altogether empirical; and, in fact, what can be recommended against an hereditary disorder? We must either abandon the suf-

ferer to his unhappy lot, or to a system of treatment which is as painful as it is often without the slightest effect.

FRACTURE OF THE OS HYOIDES.

Reduction of the fracture—Cure.

M. LALESQUE, in the *Journal Hebdomadaire*, relates a case in which he had to treat this rare accident, and succeeded *à merveilles*. A stout old seaman had a scuffle in a drinking bout, and was seized by the throat by his adversary; something gave way with a sharp noise, and acute pain was felt in the part compressed. The man could not speak, but pointed to the seat of suffering; nor could he swallow. Medical assistance was called in on the second day, when the nature of the case was ascertained, and general bleeding and fomentation were adopted. M. Lalesque resolved to attempt reduction of the fracture. He put the patient sitting in a chair, and kept his mouth open with a roll of linen. He then introduced the fore-finger of the left hand till he fixed it upon the fractured part, and with the right making firm the body of the bone, by a slight motion from within outwards he managed without much difficulty to restore the fragments to their places. But how to keep them there was the problem. He prescribed absolute rest, and abstinence. Next day the patient was bled again. The symptoms were favourable, but the man was parching with thirst. Desault's sound was introduced into the stomach through the right nostril, and left there; through this he was fed for many days. In about three weeks the sound was withdrawn; deglutition was now possible, and practised sparingly. In short, the patient went on very well, and in the course of two months was quite well.

We find a similar case in our cotemporary and namesake of Berlin; but the fracture was here more serious in its circumstances and its result. It is briefly reported by Dr. Marcinkowski, of Posen.

Fracture of the Tongue Bone—Injury to the Nerves—Death.

An elderly woman was carried into the Hospital of the Sisterhood, in Posen: she was labouring under fits of suffocation, blue in the face, and cold in the extremities. She could neither swallow nor speak, yet her consciousness was unimpaired. She died in twenty-four hours. All that could be learned about her was, that she had been driven against a wall by a wagon, which overturned upon her. There

was fracture of the left under-jaw, and some contusion of the neck: no other external injury could be detected. Upon examination after death, it was found that the left cornu of the os hyoides was fractured, and the nerves of the larynx seemed to have suffered from the contusion. No other lesion could be discovered to which the cause of death could be attributed.—*Medicinishe Zeitung.*

LECTURES

ON THE

THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE NECK AND
THROAT.

—
TRACHEITIS—CROUP.

ACUTE inflammation, gentlemen, of a very violent description, when it attacks the larger portion of the air-tubes, in children is situated, for the most part, lower down than when it occurs in adults. That intense, violent, adhesive inflammation—inflammation, at least, causing a portion of fibrin to be thrown out—which attacks adults, usually affects the larynx; so that laryngitis is the disease of adults; and the disease of children, corresponding with this, is croup, *cynanche trachealis*, or more properly tracheitis. The latter term is the most simple, and every body knows what is meant by it. The disease has been called *angina trachealis*, because there is a quantity of lymph formed: in this country it is called *croup*; in the East, I understand, and perhaps in other places, it is called *roop*.

Symptoms.—This disease is marked by a rough, clanging, ringing cough—a cough giving you the idea of sound conveyed through a small brass pipe. Besides this cough, if the disease be severe, there is hissing, sibilous respiration; but it is in the inspiration chiefly that it is heard. It is harsh, rough, shrill, or hissing; there being various modifications. The voice, too, is either harsh, crowing, or nearly suppressed. There is a difficulty of breathing, and this is felt particularly during inspiration. These are the most com-

mon symptoms. There is no difficulty in swallowing; no pain in the throat, except at the lowest part; no pain in the larynx, where there is always pain or tenderness in laryngitis: but in croup, at the lowest part where the trachea exists, there is frequently pain on pressure. The expectoration is mucous, sometimes with fibrin and shreds of lymph.

As this is a violent disease, there is violent pyrexia. During the first stage the face is flushed, the pulse is rapid, and there is great anxiety of countenance. Sometimes the peculiar clanging cough is heard for some days before the child is ill enough to shew its complaint; so that many mothers have been surprised, on being told by a medical attendant, who was accidentally in the house, and heard this peculiar cough, that the child was in danger.

Duration.—The disease may last from twenty-four hours to three or four days, or even several days, and the child may die either completely exhausted, or be suddenly cut off in a moment by spasm. Just as death sometimes occurs suddenly, so does amendment. Generally, patients recover by degrees; but sometimes they recover very rapidly, almost suddenly. When recovery is exceedingly slow, shreds of fibrin are perhaps spit up for several weeks.

Morbid Appearances.—On examination after death, we find, of course, redness of the trachea; and such is the intensity of the inflammation, that lymph lies upon the red membrane, sometimes forming a complete tube, and even extending into the bronchiæ. Besides this tube of lymph, which is so continually seen, we frequently observe a quantity of puriform and even bloody fluid in the air-tubes. There is not merely a secretion of fibrin, but likewise of puriform fluid, exactly as occurs in a serous membrane. When you open an inflamed serous membrane, you always see lymph lying upon the affected part; but, besides that, you always see more or less turbid serum,

even so thick and yellow as to approach to pus; and sometimes there is pus. So in a mucous membrane, when it is inflamed very intensely, besides fibrin you see a quantity of thin fluid inclining more or less to pus, till at last you see actual pus; you also see a bloody fluid.

Usual period of occurrence.—This disease occurs chiefly in children, between weaning and puberty. It is occasionally seen in infants at the breast, but more frequently not till they are weaned; and Professor Home, of Edinburgh, says, that the sooner children are weaned, the sooner they are liable to it. They have more experience at Leith than we have here, and observations are, therefore, more easily made there than here. It chiefly affects those of full habit of body.

Cause.—The cause is undoubtedly, in almost every instance, cold and wet; it occurs, therefore, more frequently in winter and spring than at other times: and if it occur in summer, it is generally when a damp evening has succeeded to a hot day. It is seen most frequently in a situation near the water side—in fact, in all damp situations. It is more frequent, too, in northern than in southern latitudes. It is sometimes epidemic; that is to say, a great number of children, in particular seasons, are affected with it. You know that an endeavour has been made to pervert the word *epidemic* from its common original meaning—that which attacks people at large. In that sense you have a peculiar signification, so as to distinguish between epidemic and contagious diseases; but contagious diseases may be epidemic, not from this cause or that, but merely because they extend temporarily over a whole district at once. But although this disease is frequently epidemic, I cannot believe that it is ever contagious; at least, I have never been able to satisfy myself that such was the case. It certainly does often affect more than one in a family at once; but this may only arise from all the children in the family being exposed to the cause at the same time, and from another circumstance—that there is a constant tendency to it, and therefore children in the same family may be supposed liable to the same disease. Now and then a peculiarly striking circumstance takes place, and we are inclined to believe that the disease must be contagious; but I think mistakes are frequently made in the case of croup. I will not say that it is *never* contagious, because I have not seen every circumstance that other people have; but, from what I have seen and read, I cannot persuade myself that it is contagious. It is a fact, that many children have it in the same neighbourhood, but then they have been visited with the same vicissitudes of atmosphere; and the thing

may thus be explained. And when it occurs in the same family this circumstance might explain it, together with the additional circumstance, that all constitutions are predisposed to the same disease. I know, too, that several children in a family will have it, but at different times; and some of the children in a family will be sure to have it; and therefore I presume there is a constitutional tendency to it, just the same as in inflammation of other parts.

Professor Dupuy says, that it once occurred in dogs at Alfort, and that the same appearances were observed in them as in human beings.

Treatment.—The treatment of this disease must be energetic and decided, just as I stated was requisite in laryngitis. It would be right to bleed from the arm, or jugular vein, perhaps, and apply a number of leeches over the throat; to consider it as an inflammatory disease, that must be treated briskly. I would make the same observation respecting leeches that I did yesterday. I should prefer leeches to a blister, and general bleeding to local; but I should follow up general by local bleeding. After the leech bites had bled well by means of a poultice, I would repeat them, if necessary, and then apply a blister. There is extreme danger here; and therefore mercury should be given with the greatest freedom. You will find, whatever disputes there are about mercury, that in acute hydrocephalus, in laryngitis, and tracheitis, mercury is of the highest importance. Children will bear a larger quantity of mercury in proportion than adults, and it would be right to give a child as much as it would bear, every two or three hours, without vomiting and purging. This is a much better practice than emetics. Many cases will get well with emetics, but this will be successful in a larger number of instances. The warm-bath is useful, but it is not of high importance; and, when the leeches have bled well, some have advised applying cold to the throat. I should think there can be no impropriety in it. Seeing the good effects of applying ice even to the heads of children, there can be no impropriety in applying ice in a bladder to the throat; but I have no personal experience of it.

Some have recommended bronchotomy in this disease, but I believe it generally fails. Unfortunately there is in this disease, besides laryngitis and tracheitis, frequently inflammation lower down; that is to say, the bronchial tubes, in their minute ramifications, are frequently affected at the same time, so that that portion of the disease will kill the patient, even although you subdue the inflammation of the trachea. Bronchotomy can only be a temporary

measure; it may enable the patient to breathe well for the time; but of course it can have no effect upon the inflammation. If the disease were not so extensive it might be beneficial, by giving you time to cure the affection; but, unfortunately, you frequently have inflammation of the trachea, larynx, and all the ramifications of the bronchiæ, so that it is hardly possible for the child to recover from such a mass of disease. However, bronchotomy has been tried in many cases, and failed, and I have myself employed it without success. You will find a number of cases mentioned where it was of no use, though it occasionally appears to have been so. You will find one instance recorded in the *Medico-Chirurgical Transactions*—there may be more—by Mr. Chevalier, who made an opening into the trachea, the consequence of which was the discharge of a quantity of viscid bloody fluid, and the patient speedily recovered. If, after the ordinary treatment of the disease,—good bleeding, mercury, blistering, the application of cold, and, if you choose, the administration of emetics,—if you cannot make the mouth more tender, nor bleed any farther, and yet the child is dying,—it would be better, if the friends would allow it, to make an opening than not, in order to give the patient a chance;—but, in a great number of cases, it is a very slender chance indeed. I would not do it till I had told the parents that the child would die without it, and most likely die when it was done; because otherwise it would be said, that you had cut the child's throat, and killed it. It is a frightful thing to make an opening in the air-passages, unless you prepare the patients, or their friends, for it.

In America, they recommend a decoction of seneka in this disease: but this is a stimulating substance, and, if it does good, I cannot believe that it is in the active inflammatory stage. When the inflammation is subsiding, and great secretion is going on, it may stimulate the parts and brace them up; but I have not been tempted to give the remedy in the active acute form of the disease.

Spasmodic Croup.

Symptoms.—This disease, however, occasionally takes place without any inflammation, or at least any important inflammation. Children, who have once had the croup, will frequently, on catching cold, have a crouping cough, a little hoarseness, so as really to labour under the signs of croup; but you find in such cases that the pulse is not quickened, and the child is not particularly ill. If a child have once had the croup, there is in general little fear from other attacks. If parts have been once

inflamed, they soon fall into a state of inflammation again; but then it is not active, and sometimes the inflammation is scarcely perceptible, and the disease appears to be almost entirely spasmodic. I have known children have six or seven attacks of croup.

Treatment.—It is always safe in these cases to apply antiphlogistic treatment—not vigorously, as in the first instance, but to put a number of leeches on the throat, and administer calomel once or twice a-day, and if you choose, an emetic. These means generally dissipate the disease. I know that some patients neither require leeching nor purging, and you benefit them at once by an emetic. A slight inflammation has occurred, it has thrown the parts into a state of spasm, and an emetic will frequently cure it; but it is generally safer, unless you know that an emetic has cured the child before, to apply leeches to the throat, and give it a dose or two of calomel. You are never sure that it is merely a spasm. You cannot tell that there is not some little inflammation, and you cannot tell that it is not increasing, and therefore it is the safest plan to begin with this treatment. If the child be not worse, but plays about, then the best thing is to give iron. Iron is a good thing to lessen morbid irritability in any part of the body. If there be inflammation it will do no good; but if there be mere morbid irritability, I know it is one of the best things. I shall have occasion to state, that that spasmodic cough, which is of a ringing character, yields the most readily to iron. It is best not to begin with it, but to adopt antiphlogistic treatment a day or two, and then you may give iron safely. You may give the carbonate in treacle, or the sulphate in sugar, or in tea. Children will sometimes not take it without.

ORGANIC AFFECTIONS OF THE LARYNX AND TRACHEA.

Now besides simple inflammation of the larynx and trachea, these parts are subject to various organic diseases. The larynx is frequently in a state of ulceration; not unfrequently there are excrescences upon it, looking, to all appearance, like warts: they are the same as warts on the genitals. Sometimes scrofulous tubercles form there; sometimes you have scrofulous abscesses formed in the cellular membrane, and sometimes you will have cancer and melanoid deposit.

Difficulty of making a Diagnosis.—Now as far as I know, it is impossible to make a diagnosis during life, in the greater number of cases, between simple chronic inflammation of the larynx and these organic changes. You find a person with tenderness of the larynx; you find him hoarse;

you find his voice perhaps reduced to a whisper; you find him cough a great deal, and it is ragged or shrill; you find him waste away, his pulse perhaps constantly quick; and you find tenderness, shewing altogether that the larynx is diseased: but I confess that I am not able to distinguish between simple chronic inflammation of these parts and ulceration, or the existence of excrescences, or the existence of various deposits. Others may be able to distinguish these cases, but I cannot.

Treatment.—In the commencement of such cases I should recommend you to apply the remedies of chronic inflammation, repeating leeches over and over again; blisters afterwards, if you choose; a seton in the neighbourhood of the larynx, and the exhibition of mercury; narcotics, of course, to lessen the irritation. If these things do no good, if you find the patient get worse, notwithstanding you are applying them vigorously, that the corporeal strength is decaying, and the symptoms in the throat so far from diminishing are increasing, then you may suspect there is organic disease, and generally you will be right. It is only in the latter stages of the disease that any distinction can be made: when my remedies fail, I then begin to think there is organic disease.

Occasionally the larynx is ossified. Sometimes it becomes completely ossified, and deglutition is rendered very difficult—the larynx becomes more or less immoveable—it cannot move up and down; the passage of the tube becomes so much diminished that the patient can scarcely swallow, and indeed he dies of the disease. The trachea, likewise, sometimes gradually becomes ossified, and all the various diseases that I mentioned under the head of organic affections, occur here—melanosis, scirrhus, cancer, and encephaloid disease. But more frequently we have thickening of the mucous membrane, induration, considerable excrescences, and serofulous tumors, and then the common effects of inflammation, ulceration, the formation of abscesses, and, finally, a carious state of the cartilages.

CATARRH.

The next disease, gentlemen, to which I shall call your attention is catarrh, common cold.

Character.—Now this is a very slight inflammation of the larynx, trachea, bronchia, and mucous membrane above these parts, and that portion called the *Schneiderian membrane*, having been detected by Schneider, and not only that, but the membrane of the frontal sinuses, and even of the conjunctiva of the eyes. The inflammation in this disease is not by any means so intense as that which occurs in

laryngitis and tracheitis, but is an instance of common inflammation of a mucous membrane. It is in general a very slight disease, but it extends through the whole tract from the conjunctiva of the eyes, running down the lachrymal canal, and not only affecting the membrane of the nostrils, but with them the frontal sinuses and the throat, tongue, larynx, trachea, and bronchia. It is a very slight inflammation, but as it affects such an extent of surface you will find dangerous symptoms more frequently than you are aware of.

Etymology.—This in medical language is called catarrh from *καταρρεω*, to flow down, and in common language we call it “a cold.”

Symptoms.—There is a feeling at the same time of soreness throughout the body, and generally there is tenderness of the surface, which makes the person uneasy if he press much upon any one part. There is stiffness, and an aching of the whole body; it is, however, chiefly felt in the back of the neck. There is likewise headache—I presume, from the congestion in the frontal sinuses: perhaps there may be more or less congestion within the head, but I should think that it arises chiefly from congestion of the frontal sinuses, at least that the former is inferior to the latter. There is likewise chilliness and morbid heat; the patient is chilly, and creeps towards the fire, and yet if you touch him he is hotter than he should be. If you make the observation yourself, you will find this to be the case; but there is great sensibility of the surface, so that the least breath of air blowing upon you makes you cold. The mind also is affected. There is heaviness of the head; sometimes it amounts to stupor; people are quite stupid. From the state of the conjunctiva there is frequently stiffness and smarting of the eyes; and there is, from the irritation of the membrane within the nostrils, sneezing. There is also, from the disturbance of the membrane, loss or impairment of smell, and apparently of taste: people tell you they can neither smell nor taste. I believe they can taste, although they cannot smell. Many things may be smelt as well as tasted, and these are tasted just as acutely as before. From the inflammation in the air passages the breath is hot, so that when you have a cold, if you expire the air from the lips you find it hot, as though it came from a hot place. There is generally, too, hoarseness, some cough, and a little soreness at the front of the chest. When the mucous membrane is inflamed, it is sore at the division of the trachea, and you find soreness in the situation of the larger branches of the bronchia.

Now all the parts that I have mentioned discharge; they are all covered with

mucous membrane, if the conjunctiva can be considered a mucous membrane; they are all in a state of slight inflammation, and therefore in a state of discharge. The eyes run, called *lachrymation*; and there is a discharge from the nose, called in Latin *distillatio*, or, as we say, *catarrhus*: the discharge, too, from the nose, as well as the distillation, is called *coryza*.

At first the secretion is limpid, like drops of water from a rock; it is thin and transparent, and afterwards it grows more copious and thick. As the symptoms decline, the quantity of the secretion of course declines; and, as all the symptoms go away, there frequently arises a little inflammation about the mouth and nose, and an eruption; so that the common people make the observation, and say the cold is going, because there is a breaking out about the mouth. When the cold goes off, and the inflammation within ceases, it is very common for slight inflammation to take place of an herpetic character about the mouth. During the existence of the disease the tongue is white, the skin dry, and the urine red, and when all is declining, the urine has a lateritious sediment, the common symptom of inflammation. There is also a loss of appetite. The stomach is much affected in this disease, people cannot eat, and sometimes there is also an affection of the mucous membrane down the œsophagus and stomach. There is heat and pain there, and tenderness on pressure. The pulse during the disease is quick.

Now the affection has a disposition to begin above, and travel downwards, so that persons know very well which part of the mucous membrane is inflamed at different times. When it is the mucous membrane of the frontal sinuses and nose, they say it is in the head, they feel so heavy and stupid. Then that goes off, and they begin to cough. As it leaves the upper part it generally increases in the lower, and then, after a tickling in the throat, and hoarseness, there is frequently pain down the front of the chest, and cough, and also more or less difficulty of breathing; and after that the tickling of the throat is diminished. But though it travels downwards, it frequently mounts up again. Sometimes people are beset with it in all parts at once, but generally, if the disease be slight, you see it travel downwards; and if a person have a relapse, it will come again above; but then people say they have caught a fresh cold.

Duration.—The disease will last from twenty-four hours to some weeks, and sometimes it is the forerunner, as I stated before, of violent inflammation of the larynx, sometimes of the bronchiæ. It is

often the prelude to various active inflammatory diseases.

Causes.—The common cause of this affection is the application of cold, especially when united with moisture; and, again, especially when the body is overheated and per-piring, and more particularly when it is applied partially. Many persons have a common cold in a few minutes, if exposed to a draught; but they will bear exposure to the air without any such effect. Mere cold will cause it, without any subsequent application; because, when you sit in a room without a fire when you ought to have one, the nose will begin to run before you go into a room with a fire; but while you remain there you begin to sneeze, symptoms of catarrh come on, proving the action of the cold itself. Most probably the constriction of the skin being so great, the Schneiderian membrane passes into great activity. Change of residence appears to increase the susceptibility to the disease. Some susceptible people always take cold if they change their residence, and some will catch cold without leaving their beds.

Treatment.—The best mode of treatment is to keep the body perfectly warm, so as to get rid of the chilliness. It is usual to increase perspiration by wine and brandy, and stimuli; but it is better to do it by caloric itself. The warm-bath or a vapour-bath is very good, and a local bath is also very proper; and when you are warm, plenty of hot liquids, without any wine or brandy, are exceedingly useful. If you put wine and brandy into hot liquors, there will most likely be headache afterwards.

During this time a person loses his appetite, and therefore nature indicates that he should take but little food, and that that should be chiefly fluids and of a weak nature. When a person has been ill any time, one of the best modes of getting rid of the cold is by perspiring through exercise—exercise in the open air; or good exercise, at any rate, so as to produce considerable perspiration, is one of the best things. But great care must be taken in this particular not to catch cold when perspiration is induced: if a person allow himself to cool suddenly when he is hot, his last state will be worse than his first. Good brisk walking, or dumb bells, or battledore and shuttlecock, or skipping, are highly serviceable. The patient should be careful to keep himself warm afterwards, or he will catch cold upon cold till the most serious effects are produced.

INFLUENZA.

This disease is sometimes epidemic, and then it goes by the name of influenza. We have numerous returns of this epide-

mic catarrh throughout Europe, and it is not confined to the human race, but horses, dogs, and cats, are all liable to it.

Symptoms.—The symptoms are usually more severe than in common catarrh: when the disease is epidemic, it is not so slight as when sporadic. When epidemic, there is generally complete loss of appetite, great lassitude and debility, and a very severe cough. It will attack persons both out of doors and in doors indiscriminately, and also individuals at sea. Sometimes it affects every member of a family at once, and sometimes it affects them in succession. There was a very remarkable influenza in England in the year 1782; there having been one in the East Indies and China in 1780. It appeared to travel (as many epidemics do) westward, having made its first appearance in the east. Respecting that epidemic, it is mentioned that an East Indiaman (the *Atlas*) had its crew attacked while sailing from Malacca to Canton; and when it arrived at the latter place, they found that the people had all had influenza there about the same time that the crew had had it at sea.

Differences of opinion as to its being contagious.—The above was an argument against the disease being contagious; for if the people had it out at sea, and found, when they arrived at a distant part, that the inhabitants had had it about the same time, it shews that it must have been something atmospheric, and not anything communicated from man to man. There has been a great difference of opinion respecting the contagiousness of different influenzæ: some contend that this and that influenza is merely epidemic, and others, that it is epidemic through its contagious nature. We have had epidemics of this description, but I never saw any thing to make me believe that the disease was contagious; but I should be sorry to deny it merely because the cases that came under my notice did not appear to be so. You will find, in medical books, strong facts to shew that it is contagious; and then there are others, equally strong, tending to shew the contrary; just as is the case now with regard to cholera.

Attacks persons of all ages.—The epidemic influenza attacks people of all ages, but children less than others. It is sometimes fatal to persons who have chronic disease of the chest. An influenza is sufficient to stir up inflammation when it exists in any part of the body.

Duration.—The disease lasts, when it is not epidemic, but sporadic, from a few days to a few weeks; and when it is strictly epidemic, it generally continues for a few months.

Cause not known.—What the cause of it is, I do not know.

DISEASES OF THE CHEST.

BRONCHITIS.

When inflammation attacks the air-passages at large, and particularly those within the chest—the ramifications of the bronchiæ, and affects these latter very severely, the disease is termed “bronchitis,”—inflammation of the bronchiæ.

This is the most common kind of inflammation of the lungs: the far greater number who have what is called inflammation of the lungs, have inflammation of the ramifications of the bronchiæ, so that there is now nothing heard of but bronchitis; whereas we formerly used to hear only of pneumonia, or peripneumonia. But since it has been ascertained that the inflammation which we every day see resides in the mucous membrane of the bronchiæ, the word “inflammation of the lungs” has fallen into less frequent use, and we have instead the term “bronchitis.” Certainly one portion of the substance of the lungs is made up of the bronchial tubes, and therefore the term “inflammation of the substance of the lungs” is very proper, because those tubes are an integral part of the lungs.

General Symptoms.—In this affection, which you see every day, the breathing is quick and shallow: to make up for the shallowness, the patient breathes quickly. If the patient breathe deeply, the mucous membrane is put upon the stretch so much that it occasions great uneasiness; he is more comfortable by taking a small quantity of air into the chest, but it must be accomplished more frequently than ordinarily. There is a sense of constriction of the chest, and soreness frequently about the larger bronchiæ. It is sometimes difficult for a patient to lie down, but in other cases he can do so perfectly well. There is every variation as to cough. In some persons you will see intense cough tearing them: if they even turn a little in bed, it shakes the bronchial membrane sufficiently to produce cough. Some cannot turn—some can scarcely lift their arms—they cannot produce so slight a motion of the chest as that without experiencing cough. The cough of other persons is by no means severe; if it be severe, people are confined to their bed, but if not, the motion of exercise of course makes the breathing more difficult.

From the first there is some expectoration; the mucous membrane cannot be so irritated without secreting more than it should, and this expectoration may increase to a very great amount. If the inflammation become very severe, it diminishes again, but still the patient has more secretion than in health. If a person have a very active inflammation the

secretion diminishes, and then, when the disease declines, or degenerates into the passive or atonic form, the secretion may become immense. At first it is thin, but it soon becomes thick, and frequently of a very yellow colour, so as to look almost like pus; only it is very glutinous, and swims in water for the most part. You may see it very black, as black as if soot had been mixed with it; but there are various other shades—blue, green, yellow, and white.

This expectoration is not excessively tenacious; it is certainly viscid, but not so tenacious as when the air-cells are inflamed. In the latter case, the matter is so tenacious, that if a person spit into a vessel and turn it up, it will not run, but adhere to the sides.

From the violence of the cough and the congestion, there is no longer a probability of the disease affecting the mucous membrane above. There is headache (and sometimes very violent headache) when the cough takes place. The headache is of that character, when it exists at all, that patients almost always describe it as a splitting headache; and sometimes there is drowsiness. There is great congestion in the head, and a more or less inflammatory state.

The pulse is accelerated; you may have it at 100, or even above that. As the inflammation affects a mucous membrane, the pulse is generally large and soft; of course it may be hard—there is great variety in these things—but for the most part it is full, and rather soft, or at any rate not a firm pulse. There is not the softness of debility, but a pulse of no remarkable power. The skin is frequently dry, and, of course, the tongue is dry, and generally of a dirtyish white colour, and sometimes it is covered with a great deal of mucus. The skin for the most part is hot, and now and then you see persons sweat violently. The face too shews great congestion; general congestion probably takes place, for in many cases there is drowsiness and headache, and there is likewise redness and fulness of the face. At the moment of coughing you see the veins of the temples and neck greatly distended, and the whole face become turgid. If the disease go from bad to worse, the patient cannot lie down at all; his face becomes livid, from the congestion; the lips become purple; and I have seen the face become really black—of such a hue, that I could not have believed it had been the result of bronchitis if I had had it represented to me—as dark as when a patient has taken nitrate of silver to a great amount, or there has been a communication between the two ventricles of the heart. The pulse at last becomes weaker and softer, and at the very last vermicular; the surface becomes

blue, and both the forehead and chin are bedewed with a cold clammy perspiration. In this state of things the expectoration becomes very scanty, or ceases altogether, not because it is not secreted, but the patient is too weak to expectorate it, so that he is almost drowned inwardly by mucus. In cases which are left to themselves, or badly treated, it is said that about the fifth or sixth day dyspnoea comes on, which is followed by death.

If, on the other hand, improvement take place, the constriction is removed; the cough is not much diminished, but it does not hurt the patient as it did; there is copious expectoration; the pulse becomes slower and softer, without however becoming so soft as in health; the surface perspires, and the tongue becomes moist; still, if the case be severe, there is a discharge of stuff which appears puriform.

In other cases the patient neither gets well nor dies, and then there is considerable expectoration; still the pulse is kept up, and still it is hard. In consequence of the cough he does not gain strength, but perhaps becomes more and more emaciated; he has night sweats, and at the end of many months he may die, or get all but well, and then when he is exposed to a common cold, he may have difficulty of breathing and more or less bronchitis, so that some persons who have been ill will never be able to get through a winter without an attack of asthma—that is, shortness of breathing.

Auscultatory signs—various rattles.—Besides these symptoms, however, there are others which may be learned by the ear. If you listen to the chest of a healthy person, you hear at every inspiration and expiration a slight murmuring, and this is called the *respiratory murmur*. If you listen to the breathing of a child, you find it louder than in adults, so that it has derived the name of *puerile respiration*, to distinguish it from the respiration of adults, on account of the difference of sound with which it is accompanied. I believe this arises from the fact, that there are a greater number of air cells in children, in proportion to the size of the lungs, than there are in adults.

Now if the tubes through which the air passes are altered in diameter, or there are more contents in them than usual—if instead of being moistened there be an abundance of mucus, and mucus of a different consistence to what it usually is, you must suppose that there would be a difference of sound from that which is observed in health. As bronchitis is an inflammation of the inner surface of these tubes, you necessarily have a very different sound in this disease from what there is in health. If you listen over the part that

is inflamed, you hear, instead of the natural murmur, a sound both louder and rougher than natural; and if the inflammation be very great, you then have the sound so loud and rough as to be a *snoring* sound, as if some little animal were snoring. That is called the noise of *sonorous* respiration, or rattle; or some choose to use the Latin word *rhonchus*; and some say *râle*, and would not say *rattle* for the world, because it is not scientific. However, you have a rough snoring sound, something like the bass string of an instrument. Besides that, you frequently have a shrill sound—a squeaking or shrill sound, something like the chirping of a bird, and that is termed *sibilous rattle*. It is frequently shrill, like the noise made by a grasshopper. One or both of these phenomena we constantly observe. Of course you do not hear them all over the chest, but only at those parts where the tubes are affected.

There is another peculiar circumstance in this affection, viz. that all at once, while you are listening, you will occasionally find the sound entirely cease; and if you continue to listen, you hear it again as before, or if you make the person cough, you then hear the sound of respiration again. Now this is peculiar to this disease, and it arises, it is supposed, from a large tube becoming obstructed by mucus—becoming internally temporarily obstructed by mucus, so that its ramifications get no air, and, of course, if the mucus be removed, the air enters as before. If you ever find the sound of respiration cease in a part, if you only make the patient cough, that is generally sufficient to dislodge the mucus, and the respiration returns. This is called by Laennec a pathognomonic sign of this disease.

If you strike over the chest, in old persons more especially, with the intervention of some solid body, you have a hollow sound. The sound is much increased if a piece of ivory be laid on the chest, instead of striking the bare chest. If you strike with the fingers, you have a loud sound; but a piece of ivory is one of the best things you can employ.

Now when you have hydro-thorax, or a deposition in the lungs, of course if you strike the part, in lieu of a hollow you have a dead sound, as if you struck the shoulder or thigh. In bronchitis the sound on percussio is not altered; if you strike over every part of the chest, you find it sound as in health. At the very moment even at which you may cease to hear respiration at one part, if you strike that part you still hear a hollow sound, and for this reason—although respiration is not going on, there is air there; there is no fluid collected, no solidification of the lungs, but the air is there

much as it is in health, and therefore on striking you have the natural hollow sound.

Now you have this *wheezing*, as we call it in English, not only when the person is speaking, but in a much more marked degree when he is coughing. If you have a doubt about the nature of the disease, as to whether it is bronchitis or not, because you do not hear a wheezing in the chest, such as sonorous or sibilous rattle, if you make the patient cough, you may then tell the nature of the case to a certainty. In coughing there is generally a more violent respiration, and as soon as you produce that, it will have the desired effect; and therefore, if you be not quite sure as to the nature of the complaint, it is always well to make the patient cough. You will also frequently find this disease at the back and root of the lungs when you will not find it any where else. In that situation continually, both in respiration and in coughing, sonorous and sibilous rattles are heard, when they are heard no where else.

For the purpose of listening to the chest, in order to hear these things, some employ the naked ear, but it appears to me that it would be better to employ the intervention of a foreign substance—of a piece of wood. I think if you only employ the ear, you cannot come on every part of the chest so frequently as you wish, and it is not so convenient. If the patient be a young lady, and you be a young gentleman, perhaps mamma will not be pleased at you laying your ear on the daughter's bosom; and if the patient be a greasy old fellow in the hospital, you would not like it. Upon the whole, therefore, I think it much better to employ a piece of wood.

I do not think that persons who use the ear only, do so well as others. I have known such persons give extraordinary opinions; and a great many of them are not capable of saying which instrument is the best. When you listen to the sounds of respiration, it is always best to take out the plug, and it is advisable to have the hollow extremity placed on the chest, for the sound is much increased by it. There are instances in which you expect an excavation, and you must then put on the top. I need not say that, in most instances, persons can tell a case of bronchitis without this, but sometimes you cannot. Sometimes a patient will breathe quick, and the pulse will be quick, and yet you are at a loss to say what the disease is. Sometimes I have known it difficult to say whether the disease was in the chest or not; whereas, by listening to the chest, and making the patient breathe quickly and cough, the disease has been made fairly out. If you listen to the respiration in a case where you suppose

there is bronchitis, it is right to make the patient breathe as quick as you can, and you will then hear the sounds more distinctly; it causes still more full respiration. If you make him breathe something between a common respiration and a cough, it answers very well. It is right to make him fetch a deep inspiration every now and then.

PRACTICAL REMARKS

ON

DYSENTERY.

By T. SPENCE, 52d Regiment.

—

DYSENTERY is a disease conspicuous among those of our armies, most fatal to Europeans residing in a tropical climate, and one upon which much professional difference of opinion exists: whence it would seem to be a subject eminently deserving the attention of the pathologist.

In the present paper it shall be my endeavour to portray, in a clear and simple manner, the causes, symptoms, pathology, and treatment of dysentery, so far as I am enabled to do it from personal observation.

Howsoever the disease may be complicated by the functional or structural disorder of other organs, dysentery cannot exist without inflammation of the mucous membrane of the large intestines, with or without ulceration. This state may be induced by a variety of causes, which, having once excited the disease, may either subside or continue their operation. The first class are irritating matters applied to the inner surface of the intestines, and, by their immediate contact, exciting inflammation: amongst these may be enumerated vitiated bile, indigestible or unwholesome aliments, drastic purgatives, retained scybala, and an impure atmosphere. The second are those whereby an excess of blood is determined to parts probably predisposed: they are violent mental emotions, and the application of cold to the surface of the body. The third class consists of mechanical obstruction to the return of blood from the intestines, by means of visceral disorganization: these causes operating in different degrees, produce effects varying from simple diarrhoea to confirmed and fatal dysentery. Examples are not wanting to illustrate the influence of these various causes in producing the disease at present to be consi-

dered, and, in a tropical climate, vitiated bile may be looked upon as one of the most prominent. In the healthy state of the hepatic secretion, it passes along the surface of the mucous membrane of the intestines without exciting any sensation; but any deviation, either in quantity or quality, is immediately followed by disorder of the bowels and accompanying uneasiness; this uneasiness varies in degree, from the transient griping to the excruciating and almost constant pain: often, indeed, have patients, in expressing to me their sufferings, used Dr. Johnson's words—"that they felt as if boiling lead were passing through the bowels." This irritation cannot exist long without exciting inflammation, which must, if unsubdued, terminate in ulceration. It is curious that the large intestines should suffer most, as it were but natural to suppose that the smaller part of the canal, receiving the impression first, would be more liable to be affected; this, however, is not the case: it is probably in consequence of the secretions having a more rapid transit through the duodenum, jejunum, and ileum; or this fluid, like some purgatives—for instance, aloes—may act specifically upon the large intestines. Upon investigating the history of dysenteric patients, it will often be found, that, a short time after arrival in India, the patient felt languid and heavy, with occasional headache and giddiness, loss of appetite, and a foul tongue, and pains or cramps in the calves of the legs; he was then seized with violent purging of bilious matter, the evacuations being incessant and accompanied with severe griping and tenesmus. This state having subsided often without application to medical means, the individual felt perfectly well, and continued so for some time, but again had a like attack; which, however, not subsiding so easily, he is obliged to report himself perhaps. After having observed the evacuations mixed with blood, surely in such cases as these there can be no possibility of mistaking the cause and pathology of the disease.

Indigestible and unwholesome aliments are, either in Europe or India, a most fertile source of dysentery. Within this division may be enumerated a multitude of powerful agents, some of which produce the effect immediately, whilst others are more slow, but not less sure in effecting disorganization. Shell-fish, fruit, and

vegetables, can scarcely be taken by certain constitutions, at particular periods, without producing frequent purging. There are many persons who are similarly affected by fermented liquors, even taken in moderate quantities: thus a glass of beer, or whiskey, will often purge an individual five or six times; should they, however, be taken to excess, the effect is both more severe and of longer duration. The water of particular places has, in all times, been known to cause bowel complaints, and every practitioner must have met with cases similar to one which occurred in my practice very lately. An officer and his family, in lodgings, were all attacked in one night with diarrhoea, which, on investigation, was found to have arisen from the water they had drunk; the tendency of which to produce this effect having been previously observed by the people of the house, they had long abstained from using it, but improperly neglected to report it to my friend, who, learning by experience only, used water afterwards from a more wholesome spring, and his family had no repetition of the attack. Drastic purges, in the hands of the unskilful or careless practitioner, are frequently the cause of violent inflammation of the mucous membrane of the intestines; and I have more than once had to lament the effect of those I have administered myself. I remember once having given to a gentleman a scruple of calomel, which induced a violent attack of dysentery, and it was several days before I could subdue the irritation of the bowels. The same effect followed a dose of calomel and two ounces of salts, which were given to a friend of mine the other day by a druggist.

Although it is stated by a high authority, "that those who talk of scybala in the colon being a cause of dysentery, know little of the disease," I am not afraid to declare that I have seen many cases in which this retention had excited the inflammation; but certainly these scybala are generally expelled long before the fatal termination, and they are not to be demonstrated by the knife of the dissector.

The last division of the first class of causes is an impure atmosphere: this I suspect to be one more frequently in operation than is usually imagined; we have a familiar example of its effect in the repeated attacks to which students are liable whilst attending the dissecting-

rooms. To some, this forms a serious obstruction to the prosecution of their studies, for scarcely can they breathe the tainted atmosphere but they are seized with dysentery of the most severe description. I had repeated occasion to remark, whilst in India, the influence of a vitiated atmosphere as a cause of dysentery. At Colabah, which is a small neck of land bounded on one side by the harbour of Bombay and on the other by the sea, there is a large barrack, where his Majesty's regiment, on duty at the Presidency of Bombay, is generally quartered. The buildings occupied by the soldiers consist of a long range of pendals running north and south, to the rear of which are the privies. During the spring tides, all necessary impurities were removed by the sea at high water, but during the neap tides, when there is a less ebb and flow, the water did not reach sufficiently high; and thus an extensive surface of swamp and filth was left exposed to the vaporising influence of a burning sun, whereby a most loathsome and pestiferous atmosphere was generated, which was blown directly upon the barracks whenever the sea breeze set in. So strong was this disgusting odour on some occasions, that the rooms were only tolerable when all the windows on that side were closed. I am satisfied that this malaria was powerfully instrumental in filling our hospital, and being fatal to a number of men. A moist, and at the same time heated, atmosphere, is one particularly liable to produce dysentery, and it often gives rise to a form of a particularly dangerous character. It has, and very properly may be called scorbutic dysentery; it will generally be met with on board ships, or in insular situations within the tropics.

The second class of causes are those which excite dysentery by determining an excess of blood to the mucous membranes of the intestines; and although it may be difficult to prove how it is, we cannot deny that mental emotions have, in some constitutions, a direct influence upon the functions both of the bladder and intestines. Amongst these emotions may be enumerated fear and anxiety: the former has so long been observed, that it is almost proverbial; and, during the late epidemic cholera, many cases have been distinctly traced to fear; and I know many persons who never undergo much anxiety of mind without its being accom-

panied by great irritation of the bowels and frequent purging; therefore it is fit that these should be enumerated amongst the causes of dysentery. The application of cold to the surface can, without much difficulty, be demonstrated to be an exciting cause of dysentery. In a tropical climate, the cutaneous capillary system is highly excited, and the body is in a constant state of perspiration, from the usual temperature of the atmosphere, which, however, is liable to the most extreme variations; and therefore any individual who, from necessity or imprudence, may be exposed to these vicissitudes, will become chilled, the blood will recede from the external to the internal mucous membranes, and thus a plethora is induced, which may, nay, often does, terminate in inflammation. Dysentery is frequently contracted by soldiers from this cause. In India the guard-rooms are often small for the number of men on duty, or under confinement, and, to remain inside, may be exceedingly hot and oppressive; and soldiers being persons who, if not watched, seldom consult more than momentary convenience, are tempted to throw themselves on a bench outside and sleep that part of the night they are not on sentry: by this imprudence they take cold and awake shivering, which is often followed by considerable fever and dysentery. During the monsoon or rainy season, too, the men suffer dreadfully from this complaint, induced by wet feet and clothes; it being almost impossible, at that season of the year, for a sentry to go from the guard-room to his post without being wet through, and in this state he is to remain twenty-four hours. I knew one officer, commanding a regiment in India notorious for its healthy state, and the precautions which he took were alike creditable to his intelligence and humanity: he had gravel walks laid in every direction, between the different offices of the barracks, so that the men were less likely to get wet feet; he had fires or stoves kept on in the rooms, for the purpose of drying the clothes and airing the apartments; in fact he neglected no means, even the most trifling, in order to save his men, and he had his reward.

The third class of causes are of much importance in the pathology and treatment of dysentery; and in the consideration of this class it will be necessary to refer to anatomy

and physiology, the only sure bases of medical knowledge. As we thereby learn that all the blood returning from the intestines must pass through the minute structure of the liver by means of the vena portæ, it cannot be doubted that, if this organ be diseased either functionally or organically, it must obstruct the progress of the blood from the intestines to the heart; and thus it is evident, that when there exists in the liver any engorgement of its different vessels, any inflammatory depositions, or extensive collections of matter, it must cause a simultaneous plethora of the vessels of the intestines: indeed, the merest tyro will perceive, that to obstruct the circulation must cause inflammation to the part below the impediment. However, the grand and chief cause of dysentery to the soldier is drunkenness, for in its train follow a host of other evils: in the first place, the spirit itself acts powerfully upon the mucous membrane of the intestines, frequently producing violent vomiting and purging; as that which this class of persons obtain is generally, from its cheapness, of the very worst description, consisting either of new arrack or rum, according to the station. Besides, it is more than likely that the fellow, when drunk, will throw himself on the ground, where, being deprived of locomotion, he remains exposed to the night wind and heavy dew, both of which are in the highest degree prejudicial; and lastly, drinking is sure, either in one climate or another, to produce disease of the liver.

The symptoms of dysentery are evident, and impossible to be mistaken for any other complaint. The only difficulty is to decide upon the pathologic condition of the organs implicated: first, as to the state of the liver; and, secondly, whether or not ulceration of the intestines exists. The patient, on presenting himself at the hospital, usually reports, that for a day or two, or longer, his bowels have been much relaxed; that now his calls to the rear are incessant and ineffectual—he is strained very much, and passes nothing but slime and blood; that he is no sooner away than obliged to return; he is much griped, and has severe pain in the hypogastric region; the skin is dry and harsh; the pulse quick and soft; the tongue foul and white, with red edges, or now and then red points shin-

ing through the white coating. The urine is scanty, and the bladder irritable. In some cases the evacuations are copious, fluid, and of a brown colour, like brick-dust and water; in others, little but clotted blood is passed, mixed with mucus; small particles of lymph, in thin flakes, will be often found floating in the vessel, as also a quantity of curdy matter. Occasionally large sloughs, being thrown off from the intestines, are found amongst the evacuations; it almost invariably happens that what is passed is particularly fetid. A very short time is sufficient for a person, previously robust, to be greatly emaciated by this disease; the constant pain, straining, and deprivation of sleep, independent of the evacuations, have a most debilitating influence. There is generally great tenderness, on pressure, in one or both the inguinal regions; in fact, even without pressure, the patient complains much of the lower part of the abdomen. There is also, in some cases, pain in the region of the liver. As the disease advances, the stomach often becomes irritable, and vomiting is added to the other distressing symptoms; the skin, towards the close, often ceases to be dry, but is covered by a cold clammy perspiration, which stands in big drops upon the face and forehead, apparently forced out by the straining and pain.

The duration of this disease depends upon its violence and the previous strength of the patient, and upon the treatment adopted. I have known some persons to die in three days, and others last as many weeks and months after their admission into the hospital. When I was first shewn the intestines of a man who had died after ten days' illness, I could scarcely credit that such immense alteration of structure could have taken place in so short a time; but I was afterwards convinced by experience that the disease often either runs a very rapid course, or that it exists to a very great extent without the patient having any evidence thereof. It is the more quickly fatal in cases where the peritoneal coat of the intestines becomes inflamed: this, indeed, is a very general finale. In some instances it is induced by the inflammation communicating from one coat to another, and thereby causing considerable thickening; in others, the three coats being ulcerated through, the contents of the canal escape into the cavity of the ab-

domen. Peritoneal inflammation supervening, the dysenteric patient quickly dies.

The signs of this affection are extreme tenderness of the abdomen, with great distention; the pulse quick, small, and hard; and retention of urine, which, by the way, is always a fatal symptom in this disease, so far as my observation goes. The rapidity with which death takes place in cases of this description was illustrated in the schoolmaster sergeant of the sixth regiment. He had been ailing for some time (as was learnt after his death), but not thinking it worth while to complain, continued his occupation till he was attacked with violent pain in the abdomen, and incessant vomiting. Notwithstanding every effort was made, he died in three hours after his admission into hospital. On examination, several ulcers were found in the colon, one of which had perforated the peritoneal coat, whereby a high degree of peritonitis was quickly excited. The combination of ulceration of the mucous membrane of the intestines with a scorbutic state of the constitution, is a disease which demands the utmost attention, both on the part of the physician and patient. The symptoms are an emaciated sallow countenance; a harsh, dry skin, often covered with purple blotches; a livid colour of the integuments of the lower extremities; a red tremulous tongue; spongy livid gums, which bleed on the slightest touch; hæmorrhage from the nose; flabby ill-conditioned ulcers of the legs, and great debility; the evacuations generally containing a large quantity of blood; with other symptoms which usually attend dysenteric cases.

Dissection reveals the nature of the disease, if any doubt could previously have existed. The liver, as may be presumed, is very often found in an exceedingly morbid state, frequently containing abscesses, and often when the affection was not the least suspected. It once occurred to me to be called upon to prepare for examination the body of a man who had died of dysentery. The gentleman who had attended the case, though a surgeon of extremely sound judgment, had not the most remote conception of there being any disease of the liver. Accordingly, I introduced my hand between the liver and ribs, for the purpose of examining the parts, by which I unfortunately burst a large ab-

secess, and discharged more than a pint of pus over the neat person of my excellent superior. The first fatal case of dysentery which I attended in India was of the like kind. I conceived it to be one of pure idiopathic dysentery, but dissection shewed five small abscesses in the large lobe of the liver; this, I may observe, is the usual situation in which I have found them; indeed, I do not recollect to have seen one in the left lobe. The weight of the liver I have found to be generally from five pounds to five and a half. But the never-failing change is in the large intestines, which generally exhibit a mass of disease, from the cæcum to the extremity of the rectum. In some cases the colon is greatly contracted, often to the thickness of the little finger, particularly about the descending portion and sigmoid flexure; in other instances the whole texture is thickened, and the coats are between half an inch and an inch thick, with a firm gristly feel on being cut. I have found different parts in a state of sphacelus; this has been most frequently the case about the cæcum. The mucous membrane is invariably ulcerated, but the form and description of the ulcer is liable to frequent variation; sometimes they are exceedingly numerous, small, and round; in others, large oblong elevated sloughs have been observed, adhering with more or less tenacity to the intestines. Sometimes the least touch is sufficient to detach them, and beneath is the ulcer: I have seen these about an inch and a half long, and half an inch broad.

[To be concluded in our next.]

MIDWIFERY—CLASSIFICATION OF LABOURS.

To the Editor of the Medical Gazette.

SIR,

THE following table was drawn up for the use of a midwifery class. If you think it would interest any of the junior portion of your readers, you will oblige me by inserting it in the Medical Gazette at your convenience.

Yours respectfully,

JOHN ROBERTON.

Manchester, April 6, 1833.

In teaching practical midwifery, the subject ought to be presented before the

learner in simple and lucid order. Of students in their attendance on a first course, it may be affirmed (however good their talents) that they are necessarily in the situation of children beginning to learn their alphabet; and that teacher, I have little doubt, whose mode of instruction is most in accordance with this notion, will be found to be, *cæteris paribus*, the most successful in his attempts to communicate knowledge. The classifications of labour to be found in our standard works of midwifery, have always appeared to me artificial, and calculated rather to perplex than guide the young practitioner. To furnish general rules which shall not admit of numerous exceptions, is no easy task; but unless this is, in a measure, accomplished, classification were almost better let alone. To illustrate my meaning, I shall instance the definitions of the first two classes of labours furnished in Professor Hamilton's "Outlines of Midwifery for the Use of Students," (see Section I. page 31.) "As, in by far the greatest number of cases," says Dr. Hamilton, "the head of the fœtus is forced foremost, and the delivery is completed, with safety to the mother and child, within twenty-four hours from the commencement, such cases are termed natural." Here the definition of natural labour refers to the process in *all its stages*, as also to its *duration*; but of what use is it to the inexperienced accoucheur, I would ask, to learn by the help of a definition *after the delivery is over*, and *not earlier*, that it was natural? Surely it is preferable that he should be taught to distinguish whether the labour is natural or otherwise *at its commencement*. If he finds it natural, his mind will be at ease, so long as no accident happens to interfere with its progress; and if he find it to be preternatural, he will be on his guard, and be prepared to do what the circumstances of the case may demand. However, waving this objection, the Professor's definition admits of far too many exceptions. In numerous cases, as every one must know, more than twenty-four hours may elapse from the *shew* to the delivery, without the occurrence of any symptom in the slightest degree threatening the safety of the mother and child; while, on the contrary, difficulty and danger (as, for example, indications of the approach of rupture of the womb) will, in a contracted pelvis, fre-

quently become manifest before the expiration of twenty-four hours.

The Professor's second class is *laborious* labour. "When the delivery," he remarks, "notwithstanding the head of the infant being forced foremost, is protracted beyond twenty-four hours from its commencement, it is styled laborious." Here, again, the exceptions to the rule are very numerous. The young practitioner, if he is to be guided by it, will necessarily conclude that every case he attends differs from, and is more serious than, natural labour, as soon as his patient enters the twenty-fifth hour of her (it may be) mild and in every respect propitious sufferings. Whereas, I presume to think, he will learn, as experience is gained, that the character of labour depends much on the duration of the first stage—by which I mean the time occupied in the dilatation of the os uteri; that, in fact, owing to tardiness in the first stage, numerous mild and safe instances of parturition, in no sense deserving to be called laborious, do not terminate in twenty-four hours.

As a matter of course, the teacher of midwifery is expected to furnish his pupils with some general definitions of the varieties of labour. It ought to be his aim to limit their number as much as possible, and to see that such as he deliberately adopts are precise, comprehensive, and intelligible. These considerations, I hope it will be found, have been kept in view in drawing up the following table. Instead of embracing the phenomena of labour *in all its stages*, and with reference to *its duration*, I have preferred restricting my definitions to what is discoverable *in the first stage* of labour—in other words, to the *presentations* of the fœtus.

Division I.

NATURAL PRESENTATIONS.—The presentation is natural when, *at the commencement* of the labour, the head of the fœtus, in whatever direction, *enters* the brim of the pelvis.

Note.—When the pelvis, from any cause, is under the ordinary capacity, or the head is morbidly enlarged, the presentation (it would be better to say, the position of the fœtus) may be natural, while yet the head does not enter the brim.

Although head presentations indicate favourably, as respects the safety of the mother and child, they are not all equally

conducive to easy and speedy delivery. Hence the following order:—

Propitious in the first degree: when the anterior fontanelle is directed towards either sacro-iliac symphysis, and the occiput towards the groin of the opposite side, the vertex being the lowest presenting part.

Propitious in the second degree: when the anterior fontanelle is directed towards either groin and the occiput towards the sacro-iliac symphysis of the opposite side, the vertex being the lowest presenting part.

Propitious in the third degree: when the face presents in such a manner that it enters the brim before the bulging part of the head.

Any of these varieties of presentation may be complicated with one or more incidental circumstances; the tendency of which will be to retard labour, or to endanger the safety of the mother and fœtus, or of the fœtus only. The most important of these are,

1. Pendulous belly; allowing, at the commencement of labour, undue obliquity to the axis of the uterus in relation to the axis of the brim.
2. Rigidity of the os uteri, without structural disease.
3. Rigidity from altered structure of the os uteri.
4. Natural rigidity of the vagina and os externum.
5. Rigidity of the same, from cicatrices and other morbid alterations of texture.
6. Occlusion of the vagina from the presence of the hymen.
7. Irregular uterine action.
8. Absence of pains and of uterine action (*uterine torpor*).
9. Extra-uterine pains instead of the true uterine; occurring in the back, nates, rectum, perineum, neck of the bladder, abdominal muscles, &c. (*metastatic labour*).
10. Hæmorrhage occurring during the progress of labour.
11. Lacerations of the uterus, the vagina, or the bladder.
12. Syncope.
13. Convulsions.
14. Too great descent of the uterus, from the pelvis being unusually capacious.
15. Descent of the funis taking place at the commencement of, or during, labour.
16. The rectum loaded with fæces.
17. Retention of urine.
18. Impediment to the descent of the head, from deformity of the bones of the pelvis.
19. Ditto from natural diminutive capacity of the pelvis.

20. Ditto from one or more tumors occupying the passage from the uterus.

21. Ditto from the hand or arm descending along with the head.

22. Ditto from the foot or leg descending along with the head.

23. Ditto from morbid enlargement of the foetal head.

24. Impediment to the delivery from morbid distention of one of the other cavities of the foetal body.

25. Ditto from malformation of the foetus, or from an unnatural junction of two foetuses.

26. Ditto from inordinate size of the foetus without disease.

27. Ditto from shortness of the funis.

Division II.

PRETERNATURAL PRESENTATIONS.—When, instead of the head, some other part of the foetus enters the brim of the pelvis, the presentation is called preternatural. Such presentations may be arranged into,

Propitious for the mother, and least dangerous to the foetus: when the breech enters the brim.

Propitious for the mother and more dangerous to the foetus: when the feet enter the brim.

Unpropitious for both mother and foetus: when the shoulder enters the brim.

N.B.—Most of the occurrences which occasionally interfere with the progress or safety of natural presentations, may also complicate labour in preternatural presentations.

Division III.

ACCIDENTS WHICH OCCUR DURING, OR SOON AFTER, THE DELIVERY OF THE FŒTUS.

The chief of these are,

1. Laceration of the perineum in the direction of the raphé, but not entering the sphincter ani.

2. Laceration of the perineum, together with the recto-vaginal septum.

3. Hæmorrhage immediately following the birth of the child.

4. Hæmorrhage with retention of the placenta, from irregular contractions of the uterus.

5. Hæmorrhage with retention of the placenta, from morbid adhesion to the uterus.

6. Hæmorrhage after the birth of the placenta.

7. Inversion of the uterus.

8. Sudden death from no obvious cause.

Division IV.

RARE POSITIONS OF THE FŒTUS.

1. The sagittal suture parallel to the short diameter of the brim, the forehead resting on either the promontory of the sacrum or the margin of the pubis.

2. The ear presenting at the brim.

3. The belly ditto ditto.

4. The back ditto ditto.

CONGENITAL TRANSPOSITION OF THE VISCERA.

To the Editor of the Medical Gazette.

Port-Louis, Mauritius, 3d Nov. 1832.

SIR,

I SEND you the following case for insertion, if worthy of a place in your journal. It is, I believe, without parallel in the history of congenital malformations.

I was attending, in September last, at the General Hospital, Calcutta, the inspection of the body of a man, a half-caste, who had died under the care of Mr. Raleigh, surgeon to the hospital, of cholera, supervening, as it frequently does, on chronic dysentery. The morbid appearances were such as are usually found in those cases; but there was found a complete transposition from right to left, and *vice versâ* of all the viscera and blood-vessels of the abdomen. The liver was at the left, and the spleen at the right side; the œsophagus and cardiac extremity of the stomach were at the right side, while the pyloric end was at the left; the duodenum took its usual turns, and came in contact with the gall-bladder in the left hypochondrium; the ileo-cæcal valve was found at the left side, and the appendix vermiformis falling over the edge of the pelvis; the sigmoid flexure of the colon was at the right side; the aorta was at the right; the vena cava to the left side of the vertebral column; the foramen quadratum was to the left of the middle line of the diaphragm; the aortic opening was as usual, but the foramen œsophageum lay a little to the right of the aortic opening. The heart had been removed before these points were remarked, but did not appear to have been much altered in position. The renal vessels were varied in position, the left being the longer, and passing behind the vena cava; the left iliac was longer

than the right, and passed over the iliac veins; the right iliac vein lay to the inner side of its artery, and the left was behind its artery. No symptom during life had given any reason for imagining the existence of such a state of things. It will readily occur to every one how embarrassing it might have proved to either physician or surgeon.

I am, sir,
Your obedient humble servant,
WILLIAM HARDY.

INFLUENCE OF MEDICAL EVIDENCE ON A QUESTION OF CRIMINAL RESPONSIBILITY.

To the Editor of the Medical Gazette.

2, Regency Square, Brighton,
April 2, 1833.

SIR,

A CAUSE was tried at the Lewes Assizes on the 20th of March, of great interest in a medico-legal point of view. A girl, whose age was between sixteen and seventeen, had set fire to her master's house. The fire was extinguished without much injury, and the girl committed to prison. The master was a builder, had two children, and only this house-servant. The girl had previously borne a good character, had no accomplices, stole no property, and committed the deed without apparent motive. Her master was anxious to save her life; and a gentleman in Brighton, a retired barrister, from motives of humanity, undertook her defence. It appeared that she had been in Chichester Infirmary in January, 1832, where she was afflicted in succession with low fever, measles, scarlet fever, and strong symptoms of consumption—cough, expectoration, night perspirations, and diarrhoea. She had never menstruated, had always been of a reserved, taciturn disposition, and had conducted herself in an eccentric manner on many occasions. The counsel argued that, under such circumstances, the act for which she was tried was probably committed in a state of imbecility, or delusion of mind, in which she could not be considered a morally responsible being. To confirm this view he called two medical gentlemen, Mr. Pitt, surgeon, and myself, to give our opinion as to the effects which severe illness, and the non-appearance of the catamenia, might have upon the mind—whether in-

sanity in any form or degree ever occurred under such circumstances. The result of our evidence upon the minds of the judge, Sir N. Tindall, and the jury, was such that the girl was acquitted. This verdict was remarkable in several particulars:—1st, We had not seen the girl, and gave no opinion upon the actual state of her mind. 2dly, The verdict was founded upon an inference drawn by the judge and jury from general medical principles. 3dly, It was gratifying to see the respect paid to the medical evidence, and, through that, to the profession at large, so different from the manner in which it was treated in London within a very recent period. 4thly, It was pleasing to observe the tone of liberality and good sense with which the whole subject was considered, without the least appeal to passion or prejudice, but resting the merits of the case entirely on rational grounds, and the conclusions of calm and impartial deliberation.

I am, sir,
Your obedient servant,
W. KING, M.D.

HYDATIC CYST AT THE BASE OF THE BRAIN;

Being a remarkable case observed by M. MONTAULT, and communicated by him to the Academy of Medicine, Paris.

(Abridged from the *Journal Univ. & Hebdom.*)

THE person whose case we proceed to describe was a man of the name of Girard, aged 33, a weaver. About three years ago he was attacked with sharp pains of the posterior part and left side of the head, soon extending to the neck, and accompanied by trembling and twitching of the muscles. It appeared that he had had a fall previous to the manifestation of these symptoms, and that he hurt the back of his neck. He was obliged to keep his bed for four months, during which time he at one period experienced considerable difficulty in speaking so as to be understood. The plentiful application of leeches relieved him effectually, and he remained well for about a year. Towards the latter part of 1831, however, he had a recurrence of the pains, and upon entering the Hôtel Dieu at that time, was unable to turn his head upon his neck.

He remained under the care of M. Dupuytren for twenty-four days, and then went out much relieved by cuppings and moxas. But from time to time afterwards he was an inmate of the same hospital, and on the whole he was evidently growing worse. About the beginning of 1832 he could by no means rotate the head. The same remedies were continued, and with some improvement. Pain behind the ears; the senses unimpaired; venereal appetite nearly extinct for the last three months. He now complained of shudders, and as it were the infliction of a series of slight blows on the skin of both his sides, his shoulders, and belly; and M. Montault was induced to suspect, on the theory of Bell and Magendie, that there was some alteration of the spinal marrow in its posterior part,—whence he ordered a seton to the back of the neck. This seemed to do some good, but the case was tedious, and Girard once more grew tired of the hospital. He went out, and did not return again for six months.

In September last he came under the care of M. Rostan, and underwent a careful examination. There was pain about the occipital foramen, extending to the third or fourth cervical vertebra, but permanent at the articulation of the atlas and axis, without swelling or alteration of the texture or colour of the parts. Behind the mastoid process of the left side there was a small tumor, about the breadth of a franc-piece, and about a line or two in elevation, elastic, like those cysts which are found in the course of tendons (at the wrist, for instance), not very painful on pressure, unless when violently compressed, nor was it surrounded with bony projection, such as is usually observed in fungus of the dura mater that has worn through the bone. The pain on pressure was felt even at the origin of the vertebral canal. The voice was changed in clearness and volume, yet the pronunciation was unimpeded, the respiration easy, no cough nor expectoration. The patient complained of losing his memory in some degree; deglutition was not comfortably performed, a small quantity of every liquid getting into the larynx in the act of swallowing; but solids went down easily enough. Numbness of the left arm. General health good.

About the beginning of October the patient had hiccup occasionally, making a painful impression along the cervical

region; he began to lose his appetite, and to be affected with vomiting and obstinate constipation; hectic in the evenings: in short, the disease was now making rapid progress, yet the man insisted upon going home, where he staid about six weeks.

Upon his return for the last time his condition was as follows:—He lies as motionless as possible, in order to avoid the pain of moving his neck. He is nearly destitute of voice. Sensation impaired generally on the left side; memory affected; continual fever; sleeplessness. Dec. 25th.—Voice more diminished than ever; limbs of the left side affected with itchings and darting pains; pain above the orbits; thirst intense; deglutition of liquids extremely difficult; high fever; involuntary passing of faeces and urine; change of features. An alleviation is felt after 20 hours. An aphthous eruption shews itself in the mouth some days after, but yields to gargles.

About the beginning of January this year (1833), deglutition rapidly became so difficult that every thing he attempted to swallow threatened him with suffocation; pulse very quick; skin hot; intellect not disturbed. On the 12th, at seven in the morning, after fatiguing himself in endeavouring to swallow, or rather to suck, a little bouilli, his head fell suddenly on his shoulder: he was dead.

Examination of the body twenty-four hours after death.—*Head:* The cranium, meninges, and substance of the brain, present nothing anormal. Ventricles dilated with an abundance of transparent serum. Upon dividing the tentorium, and raising it, a cyst is perceived, having whitish, opaque, yielding walls; it is about the bulk of a goose-egg, fluctuating. Being accidentally opened, a quantity of liquid serum escapes, with a multitude of *hydatids*, perfectly round, smooth, and pellucid, their volume varying from that of a grain of hemp-seed to a chesnut. The cyst lies between the left occipital fossa, the corresponding side of the basilar surface, the left hemisphere of the cerebellum, which it raises, and the medulla oblongata, which it turns a little to the right. It has no adhesion to any of these parts, the arachnoid remaining smooth and transparent even where it has been in contact. It penetrates but a few lines into the

vertebral canal, at which place it forms a kind of appendix, like the finger of a glove, dipping into the anterior condyloid foramen, and containing an hydatid, which seems as if it would vain force the passage of this narrow strait. A second appendix is given off from the base of the cyst, which is still more remarkable. It has passed through the posterior foramen lacerum, and then turning backwards, it is found dilated into a spherical shape just beneath the superior extremity of the complexus and sterno-mastoid muscles. This was the cyst the presence of which was noticed during the life of the patient as seated behind the mastoid process. It contained numerous hydatids.

It was now thought important to examine the nerves coming out of the base of the skull. The lingual nerve was perfectly sound; the glosso-pharyngeal, pneumo-gastric, and spinal, of the left side, underwent a remarkable change upon their emergence from the posterior foramen lacerum; which was also the case with the hypoglossal; for immediately upon leaving the skull the latter nerve especially became atrophied and filiform, two-thirds smaller than the corresponding one on the right side. Nor was it the soft parts alone that suffered from the presence of the cyst—the bones were not indeed carious, but they were thinned and hollowed as they would be by the presence of an aneurismal pouch in contact with them.

Throat: The muscles of the tongue and palate, on the left side, are all attenuated and spongy, and present little of their proper structure. The œsophagus is contracted to the size of the little finger, but its structure does not seem altered. The larynx is found filled with a whitish, creamy substance, which proves to be the bouilli which the deceased had taken a few seconds before he expired. The left chorda vocalis is atrophied; the mucous membrane of the trachea red and swollen. *Chest:* Bouilli found in the bronchi, at their bifurcation, which also partake the redness of the trachea. Lungs crepitating; on the whole healthy. Heart normal in its structure; right cavities distended with black blood. *Abdomen:* The liver presents on its anterior surface a great number of irregular striæ, of a dark blue colour, resembling varices at first sight; they are, in fact, the dilated

hepatic veins lodged near the surface. On the inferior portion of the middle lobe there is an hydatid tumor, smooth, whitish, fluctuating, of tolerable size. The substance of the liver gorged with black blood. Nothing remarkable about the other viscera of the abdomen. *Vertebral column:* No deformity, or change of structure, in the vertebræ. The spinal marrow, and its membranes, perfectly sound.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

The Black Death in the Fourteenth Century, from the German of I. F. C. HECKER, M.D. &c. Translated by B. G. BABINGTON, M.D.

MEDICAL history has long been in need of the chapter which this book supplies; and the deficiency could not have been remedied at a better season. Just freed from a visitation the most alarming, and filled, as we ought to be, with a due sense of the mercy of Providence in passing over us so lightly, if we look to the records of past ages, and particularly to the accounts which have reached us of the pestilences which ravaged the world in former centuries, our gratitude cannot but be greatly heightened by finding ourselves so mildly dealt with. We have to reckon our losses, it is true, by thousands, but then thousands of thousands were the measure of the ravages sustained in former times. In the sixth century an almost incredible number of the population of the earth (Gibbon does not think 100 millions beyond the limits of probability), were cut off by a black plague; and in the fourteenth, according to the well-weighed calculation of the volume before us, Europe alone lost 25 millions of its inhabitants—that is to say, a fourth part of the whole population which it then contained!

"The Black Death" is an awful title for a true history; but there are facts in history more awful than any that romance can bring forth. Boccaccio has no tale in his Decameron more spirit-stirring than the true one with which he begins his work; nor has Defoe, in any of his plausible fictions, produced any

thing so harrowing as his description of the plague of London, in which, with whatever art they are put together, no other details are given than those which he diligently gathered from authentic sources. Professor Hecker shews himself every where anxious not to set down aught without his vouchers; he has consulted, with an industry truly German, a multitude of authorities—many of them inaccessible to inquirers in this country; but we must do him the justice to declare, that, wherever we have been able to verify his statements, we have had reason to consider him eminently trustworthy. With the “History of Edward the Third,” for example, the production of our Barnes—Joshua, *felicis memoriæ judicium expectans*—Dr. Hecker seems to be perfectly well acquainted; but he never once indulges the reader with any of the extravagancies of that laborious but credulous author. In extracting from the “tragical chapter” of the English historian, he has the good sense not to borrow a single line from the several folio pages in which the auguries, and horrible forewarnings, and the terrible aspects of the planets, are minutely recorded; and this perhaps is the more to be appreciated, as Dr. Hecker would seem to attach a high importance to astral influences—it being, in fact, a part of his theory, that a certain organism pervades all nature.

And now that we have mentioned that the author *has* a theory in this performance, we may as well let him state it briefly in his own words—and the rather, as we are not quite sure we could do it in our own with perfect understanding:—

“A cosmical origin and convulsive excitement, productive of the most important consequences among the nations subject to them, are the most striking features to which history points in all general pestilences. The latter, however, assume very different forms, as well in their attacks on the general organism, as in their diffusion; and in this respect a development from form to form, in the course of centuries, is manifest, so that the history of the world is divided into grand periods in which positively defined pestilences prevailed. As far as our chronicles extend, more or less certain information can be obtained respecting them.”

The author's views, it must be admitted, are on a grand scale; there is something magnificent—as well as much

more definite than what we have just quoted—in the following passage:—

“Were it in any degree within the power of human research to draw up, in a vivid and connected form, an historical sketch of such mighty events, after the manner of the historians of wars and battles, and the migrations of nations, we might then arrive at clear views with respect to the mental development of the human race, and the ways of Providence would be more plainly discernible. It would then be demonstrable that the mind of nations is deeply affected by the destructive conflict of the powers of nature, and that great disasters lead to striking changes in general civilization; for all that exists in man, whether good or evil, is rendered conspicuous by the presence of great danger. His inmost feelings are roused—the thought of self-preservation masters his spirit—self-denial is put to severe proof, and wherever darkness and barbarism prevail, there the affrighted mortal flies to the idols of his superstition, and all laws, human and divine, are criminally violated.

“In conformity with a general law of nature, such a state of excitement brings about a change, beneficial or detrimental, according to circumstances, so that nations either attain a higher degree of moral worth, or sink deeper in ignorance and vice. All this, however, takes place upon a much grander scale than through the ordinary vicissitudes of war and peace, or the rise and fall of empires, because the powers of nature themselves produce plagues, and subjugate the human will, which, in the contentions of nations, alone predominates.”

Of the nature of the disease characterized by the “black death,” the author gives us a more full and consistent account than we ever hoped to have obtained. From the ex-emperor, John Cantacusene, we learn that in Constantinople the disease was marked by the presence of malignant buboes, and boils, and black spots, which in many cases broke out all over the body. Symptoms of head affection were frequent; some patients became stupified and comatose, others were sleepless and turbulent. The fauces and tongue were black; there was burning thirst, and so much general suffering, that many in despair inflicted death upon themselves. Contagion was evident, for the disease was most speedily communicated to the

relations and friends of the sick, and many houses in the capital were bereft even of their last inhabitant. But there was this peculiarity about the black plague of the fourteenth century, distinguishing it from the oriental pestilence of later times, namely, that the organs of respiration were seized with a putrid inflammation; a violent pain in the chest attacked the patient; blood was expectorated, and the breath diffused a pestiferous odour.

At Avignon, when the disease first appeared there, it was attended by an ardent fever, with evacuation of blood, and was fatal in three days. Instead of buboes and inflammatory boils appearing outwardly, it was found that a carbuncular affection of the lungs occurred, which proved rapidly destructive of life. At first it raged among the poor, but subsequently attacked the more affluent classes. The symptoms of the disease in Egypt were similar.

Boccaccio's description of the plague as it raged in Florence, is well known: buboes its first symptom, and attacking both men and animals by manifest contagion. In Germany it would appear that it assumed a milder character; it was certainly not nearly so devastating there as in other parts of Europe; nor do the accounts state that spitting of blood—the diagnostic symptom of this fatal pestilence—was a symptom there; but this is probably owing to the imperfection of the chronicles.

In France the mortality was dreadful. Many were struck as if by lightning, and died on the spot, and this more frequently among the young and strong than the old. Patients with enlarged glands in the axillæ and groins scarcely survived two or three days; and no sooner did these fatal signs appear than they bade adieu to the world, and sought consolation only in the absolution which Pope Clement VI. promised them in the hour of death. Nor was the state of things less deplorable in England, in which, according to Barnes, scarcely more than a tenth part of the people were left alive. The character of the disease was here the same—boils and buboes, which left no hope for those in whom they arose in numbers. "Every spot which the sick had touched, their breath, their clothes, spread the contagion; and, as in all other places, the attendants and friends, who were either blind to their danger or heroically des-

pised it, fell a sacrifice to their sympathy. Even the eyes of the patient were considered as sources of contagion, which had the power of acting at a distance, whether on account of their unwonted lustre, or the distortion which they always suffer in plague, or whether in conformity with an ancient notion, according to which the sight was considered as the bearer of a demoniacal enchantment."

Norway became infected, through its commercial intercourse with England, and had the disease in its most frightful form—with vomiting of blood. Poland, and finally Russia, were visited by the pestilence; and it is remarkable, that the breaking out of the disease in the latter country was two years later than in southern Europe.

It seems to be universally admitted, that the "black death" had its origin in some dreadful convulsion of nature in the remote parts of Asia. If any faith may be put in Chinese annals, earthquakes, floods, and famines, raged in that empire, and committed the most terrible havoc among the population; and it should be mentioned that signs of terrestrial commotion preceded the visitation in some parts of Europe also. A pestiferous wind attended the earthquake in Cyprus, and spread so poisonous an odour, that many being overpowered by it fell down suddenly, and expired in dreadful agonies. It is certain that earthquakes at this period were much more prevalent every where than they had ever been known within the range of history, and they were of frequent recurrence in the south of Europe from the year 1348 till 1360.

In concluding the interesting chapter on the *causes* of the "black death," the author thus expresses himself:—

"This disease was a consequence of violent commotions in the earth's organism—if any disease of cosmical origin can be so considered. One spring set a thousand others in motion for the annihilation of living beings, transient or permanent, of mediate or immediate effect. The most powerful of all was contagion; for in the most distant countries, which had scarcely yet heard the echo of the first concussion, the people fell a sacrifice to organic poison—the untimely offspring of vital energies thrown into violent commotion."

That the nations of Europe, after such a fearful concussion, were enabled to de-

velop their energies to such an extent as they did in the next and following centuries, is, as the author observes, a strong proof of the indestructibility of human society as a whole. "To assume, however, that it did not suffer any essential change internally, because in appearance every thing remained as before, is inconsistent with a just view of cause and effect. Many historians seem to have adopted such an opinion; accustomed, as usual, to judge of the moral condition of the people solely according to the vicissitudes of earthly power, the events of battles, and the influence of religion, but to pass over with indifference the great phenomena of nature, which modify, not only the surface of the earth, but also the human mind. Hence, most of them have touched but superficially on the "great mortality" of the fourteenth century. We, for our parts, are convinced, that in the history of the world, the 'black death' is one of the most important events which have prepared the way for the present state of Europe."

The chapter on the moral effects of the black plague, particularly in Germany and Italy, is very beautifully drawn up. The transition from that awful sense of humiliation, which characterized the outbreak of the pestilence in every quarter, to the most rank fanaticism—then bigotted zeal—and, ultimately, the most abominable spirit of persecution, is admirably described by the pen of Dr. Hecker. His account of the Flagellants is the fullest we have seen, and the details of the cruelties inflicted on the Jews are painfully interesting. But perhaps the portion of the volume which deserves our best commendation, is that in which the state of the profession in the fourteenth century is depicted. It would seem that we have been too much in the habit of undervaluing the practical ability of the physicians who flourished at the time of this great pestilence, and to whose merits tardy justice has been at length done by the author of the "black death." It is true that the document put forth by the faculty of Paris as a body—detailing their opinion of the causes of the plague—does not redound much to their credit as a scientific corporation; but the age which possessed such able men as Gentilis of Foligno, Guy de Chauliac, Galeazzo de Santa Sofia, and Chalin de Vinario, was not without witnesses to redeem the profes-

sional character. The sketches of these distinguished lights of their age we would fain transfer to our columns, did our space permit; but we are warned by our narrowing limits to reserve some room for one more extract; it relates to the origin of quarantine:—

"The first regulation which was issued for this purpose, originated with Viscount Bernabo, and is dated the 17th January, 1374. 'Every plague patient was to be taken out of the city into the fields, there to die or to recover. Those who attended upon a plague patient were to remain apart for ten days, before they again associated with any body. The priests were to examine the diseased, and point out to special commissioners the persons infected, under punishment of the confiscation of their goods, and of being burned alive. Whoever imported the plague, the state condemned his goods to confiscation. Finally, none except those who were appointed for that purpose, were to attend plague patients, under penalty of death and confiscation.'

"These orders, in correspondence with the spirit of the fourteenth century, are sufficiently decided to indicate a recollection of the good effects of confinement, and of keeping at a distance those suspected of having plague. It was said that Milan itself, by a rigorous barricado of three houses in which the plague had broken out, maintained itself free from the '*great mortality*' for a considerable time; and examples of the preservation of individual families, by means of a strict separation, were certainly very frequent. That these orders must have caused universal affliction, from their uncommon severity, as we know to have been especially the case in the city of Reggio, may be easily conceived; but Bernabo did not suffer himself to be frightened from his purpose—on the contrary, when the plague returned in the year 1383, he forbade the admission of people from infected places into his territories, on pain of death. We have now, it is true, no account how far he succeeded; yet it is to be supposed that he arrested the disease, for it had long lost the property of the 'black death'—to spread abroad in the air the contagious matter which proceeded from the lungs, charged with putridity, and to taint the atmosphere of whole cities by the vast numbers of the sick. Now that it had resumed its

milder form, so that it infected only by contact, it admitted being confined within individual dwellings, as easily as in modern times."

It was in 1485 that the first special council of health was instituted, and that at Venice; in which city also all those regulations were gradually called into activity, which have served in later times as a model for the other southern states of Europe. Lazarettos were established, and a power of life and death granted over those who violated the rules. Bills of health, however, were not general in Europe until the year 1665.

In the Appendix are some curious materials for the inquisitive: the ancient song of the Flagellants—a copy of the extorted confessions of certain Jews, who were tortured at Chillon for the supposed crime of poisoning the wells—and finally, some extracts from Caius's "Boke on the Sweate." On the whole this volume ought to be popular; to the profession it must prove highly acceptable, as conveying so much information touching an important subject, which had almost been suffered to be buried in oblivion; and we think that to Dr. Babington especial thanks are due, for having naturalized so interesting a production. The style of the translation, we may add, is free from foreign idioms,—it reads like an English original.

MEDICAL GAZETTE.

Saturday, April 20, 1833.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

EDINBURGH GRADUATES.

A LEARNED and highly-respected contemporary has taken some trouble, with a view of rectifying what he calls "a misrepresentation—an unintentional doubtless," on our part, with regard to the Edinburgh graduates. Our readers may possibly remember that, a few weeks ago, we published a letter from Dr. Christison on the same subject; and lest there should be any doubt as to what we actually did say, we shall here

repeat it. In advocating with all our humble powers the cause of the Licentiates of the London College of Physicians, we observed, that what had given a handle against them, and made it more difficult for their friends to serve them than might otherwise have been the case, was the manner in which some of them had obtained their diplomas, owing to the too great facility with which the Scotch Universities were in the habit of granting degrees. In reference to this point, we said—

"It would not be difficult to point out Licentiates who have had no University education whatever—who have come to London to take whatever chance or fortune might send them—who have practised as surgeons, or apothecaries, or any thing; and who have either purchased their degree at Aberdeen, or (leaving their patients in the charge of a friend for a day or two,) have matriculated at Edinburgh; and by repeating the same process two or three times, have on the last occasion come back from the north full grown *Doctors*, without ever having been missed from London."

This is the passage at which our contemporary of the north has taken umbrage, and to the refutation of which he devotes several pages.

We have too much respect for the parties in question to meet the case otherwise than in a spirit of perfect candour. Influenced by these feelings, we must say that we are rather astonished at some of the comments which have been made upon our words above quoted, which, we submit, can only be fairly interpreted to mean, as regards Edinburgh, that there were some Licentiates of the London College of Physicians who had obtained their degree there without a *bonâ fide* residence. This assertion we regret to be compelled to repeat, notwithstanding the denial of our contemporary. We are called upon to name the parties; but it is quite obvious that to do so would be in the highest degree invi-

dious, and give a personal and individual application to observations of a general nature, and which were intended to refer to certain circumstances connected with the London College of Physicians—not to hurt the feelings, or injure the reputation, of gentlemen long settled in practice. We say that an Edinburgh degree has been obtained without a *bonâ fide* residence. They, on the contrary, say it “never” has; and we are content to let the matter rest, on the respective authorities of the two journals—having, however, first called attention to what follows. It is not a hundred years ago since the matriculation, performed once during the season, was the only ceremony, except that of paying the fee to the professor, by which the presence of the student was positively ascertained; and these having been gone through, the next mail to the south might carry the party who had so enrolled his name, back to roll pills in England. That such facility was “never” taken advantage of, is the fanciful belief of our contemporary; that it occasionally was so, is our statement, founded on a knowledge of the fact. But again we are told, that “the necessary monthly subscriptions, and the close surveillance of the teachers, is (are) perfectly sufficient to enforce residence and attendance.” From this we learn at least two things which are important: first, that there are “monthly” subscriptions; and, secondly, that such precaution is “necessary.” Now, at the time we allude to, there were no *monthly* subscriptions, nor, indeed, any except those above mentioned; and we cannot refrain from asking, whence their institution—whence their necessity—whence the surveillance, aye, the “close” surveillance, of the professors? Is it not palpable that these regulations have been established, and that their rigid adoption has been found necessary, to check some abuse? And what abuse

but that to which we have alluded could call for, or would be obviated by them? In giving insertion to Dr. Christison’s letter, we have already expressed our satisfaction that the evil no longer existed.

Our contemporary, however, not content with the denial on this point, speaks of the passage in the Gazette which we have quoted above, as one “which certainly conveys the idea, that a physician may graduate in Edinburgh without residence at a University, and without examination;” and this representation of our statement, as applying to examinations, is made no less than three times in the course of the article. We must protest against the fairness of this. There is no expression of ours which can, by any latitude of interpretation, be reasonably held to imply that candidates for the degree were not examined; we know too well the usages in Edinburgh to have made so erroneous a statement. Our remark applied simply to the existence of Licentiates in London, who had not *bonâ fide* resided in the northern capital during the full period of their supposed pupillage; this was meant—this was expressed—and nothing was meant but what was expressed. We are therefore disposed to regard as a piece of gasconade, the peremptory declaration, that “there never was such a thing in Edinburgh as admission to degrees without examination.”—Who ever said there was?

Nor is this the only point on which our contemporary attributes to us opinions which we have no where expressed (and which, therefore, he has no right to assume we entertain), merely, as it would seem, for the purpose of gain-saying them. Nothing is so easy as to build up a man of straw, and then most valorously to knock him down again. Thus we have some “wise saws and modern instances” illustrating the propriety of physicians being in the first

instance educated as surgeons; and Cooper and Travers, Brodie and Lawrence, we are told, practise more as physicians than as surgeons; to all of which we have not the slightest objection, except to its being introduced as if in answer to opposite doctrines advocated in this journal. It is farther assumed, that we have been upholding the English graduates at the expense of the Scotch. We submit that we have argued the cause of the latter most strenuously; and are still ready to support their just claims, which we think are not fairly met in England—or at least in London. But even in doing this, we must limit ourselves to what is really matter of fact. And this leads us to another of the sins we have committed—namely, that of having stated that the English graduate has the advantage in his preliminary academical education.

“We observe (says the learned editor) that our contemporary insists much on the advantage which the graduates of Oxford and Cambridge possess over the Scottish graduates in general, and the Edinburgh ones in particular, in the matter of preliminary academical education, and maintains, that, in order to place the latter on a footing with the former, such a course of literary education ought to be prescribed and enforced by academical statute, as might remove this alleged inequality. To this we have no objection in the world; and though we say it with humility, we have some small hopes that the average of the Scottish Edinburgh graduates, at least, would bear comparison in this respect, even with the average *alumni* of the far-famed English establishments. It is a most weak mistake to imagine, that, because preliminary academical education is not prescribed by the statutes regarding medical degrees, it is not taken. The members of the medical faculty understand that every candidate has obtained the literary education of a gentleman; and this they know comprehends the usual acquaintance with the Greek and Roman classics; a course of mathematical instruction; and the elements of natural philosophy, with ethics or meta-

physics, as may be the individual tendency. This they have not thought it proper to prescribe, no more than they thought of prescribing a course of dancing, fencing, or gymnastics. But they presume that it is obtained; and, in point of fact, a course of education still more extensive is obtained by many of the Edinburgh Scottish graduates.”

The above is a very singular passage. First, it will be observed that the superiority of the preliminary education, as to the classics, mathematics, &c. of the English Universities is called in question; next, that the medical faculty “understand” that the candidates for a degree in medicine have passed through an elaborate preliminary education, the particulars of which are stated; but, lastly, that they no more think of prescribing such a course, than one of dancing! To this we answer, in the words of our contemporary, that “it is most weak” on the part of the medical faculty, to *understand* what is here assumed; for it is contrary to the facts. Students who are natives of Edinburgh, indeed—those who have been at Aberdeen or Glasgow, and a few from Oxford and Cambridge, together perhaps with some foreigners—may have gone through this preliminary academical education; but it is quite notorious that not one in twenty of the others have had this advantage. Again, what are we to say of the value and importance attached to such acquisitions, by those who place them on the same footing as “dancing, fencing, or gymnastics.” They presume that these last accomplishments have been attained, and they also presume, that the classics, mathematics, natural philosophy, and metaphysics, have likewise been duly studied! This mode of arguing the question needs no comment; and we shall therefore conclude by declaring, that we have every good feeling and friendly sympathy towards our brethren of Edinburgh; but as we have often freely censured what is wrong—or

appears to us to be so, in the English Universities and London College of Physicians, so we must crave permission to allude with equal freedom to what is objectionable elsewhere—to root out, if we can, the weeds, even should they flourish on the northern bank of the Tweed.

ANATOMY ACT.

THE Anatomy Act having been found to work well, and having thus fully justified the anticipations of those who, like ourselves, originally supported it, measures are about to be taken for rendering its operation permanent. It appears that when the present bill was first introduced, the question as to the means of meeting the expenses created considerable difficulty, inasmuch as it was held to be an invariable rule in such cases, that the parties who reaped the benefit should bear the burden. As, however, the Anatomy Act was last year regarded as an experiment, the Government consented to the insertion of a clause, by which the expenses devolved upon the Treasury, but, as we are informed, on an understanding that if the bill were found to answer, a permanent provision should be made to meet the disbursements. To accomplish this, it is proposed that each person who enters the medical profession, should pay a stamp duty of 1*l.* 1*s.*, and that teachers of anatomy should annually pay a small fee for their licence. The principal lecturers have signed an expression of their approbation of this measure; so that it is quite a mistake to suppose (as a contemporary has done), that the teachers objected to it. Neither is the statement correct, that the Act itself is to be altered; the proposed changes are to come under the stamp department.

GOWER-STREET HOSPITAL.

SOME of the journals which are in the particular interest of the Gower-Street School have represented all those who condemn the system of grandiloquence and pretension adopted by its supporters, as having no sufficient grounds for their strictures, and as being influenced by unworthy motives in their animadversions. The announcement, confidently made at the beginning of last season, that an hospital would be opened before the commencement of the next, is one

of the points which has been particularly adverted to. In keeping with this plan it has been affirmed in the journal which may be looked upon as the especial organ of the school, that sundry large sums have been received, and that the hospital is forthwith to be begun. Now we by no means think of contradicting the latter part of this assertion, for there is no indiscretion of which the parties seem to be incapable: we shall therefore content ourselves with stating, as shewing the justice of our former remarks, that by an official announcement inserted in the *Times* of this day (April 17, 1833), it appears that the whole monies in hand, to build, furnish, and endow the said hospital, is exactly £3,104: 19*s.* The sum collected since the former announcement, some months ago, resulting from the recent exertions, comes to £615: 4*s.*, whereof the annual subscriptions amount to *nine guineas*! To those at all conversant with such subjects, comment would be superfluous.

THE INFLUENZA.

THE influenza of which we gave an account last week continues in undiminished activity, constituting by far the most extensively prevalent epidemic which has for many years visited this metropolis. We have little to add to the description of the symptoms which we have already given, nor have we seen occasion to change the opinions we then offered regarding its treatment. Under the use of saline diaphoretics, warm diluents, and a short confinement to bed, the most cases speedily lose their character of urgency, but very few pass off entirely without several days of languor and depression. We must, however, add to our remark last week against the propriety of bloodletting, that we have heard of several cases in which this has been followed by the most injurious results. The phenomena of the disease—the suddenness of its invasion—the numbers (sometimes amounting to ten, and even more, in a family) who are simultaneously seized with it—and its having swept like a torrent over the whole town—contrast very strongly with the slow progress and detached irruptions of cholera, and forcibly illustrate to all who are not blinded by prejudice the difference between a disease which is purely epidemic, and one which is contagious.

OBSERVATIONS

ON

LUXATIONS OF THE HUMERUS.

BY BARON DUPUYTREN.

From the "*Leçons Orales*," published periodically, under the Baron's inspection, and in continuation of the lecture at page 634 of our preceding volume.

THERE is perhaps no subject in surgery with regard to which authors are more divided than with respect to dislocations of the arm. This is not the place to enter into a history of those differences, and I shall therefore content myself with reminding you that experience and observation have convinced me that the arm may be dislocated in three principal directions—viz. 1, downwards, on the axillary border of the scapula; 2, inwards and forwards, into the subscapular fossa; 3, outwards and backwards, into the sub-spinous fossa. The presence of the acromion and coracoid processes, united as they are by a strong ligament, and the situation of the humeral extremity of the clavicle, are opposed to direct luxation upwards: nevertheless, Sir Astley Cooper admits a partial luxation in this direction, the upper part of the capsule being lacerated, and the head of the bone resting upon the posterior edge of the coracoid process.

The dislocation of the humerus downwards—the only one, according to some authors, which is primarily possible—is undoubtedly the most common. It is generally produced by a fall on the elbow, and still more on the palm of the hand, the arm being extended and projecting directly from the body. The humerus is then inclined on the glenoid cavity in such manner as to form with it an acute angle. The head of the bone, thus slipping from above downwards in the articular cavity, comes to be pushed against the lower part of the capsule: this, pressed in a contrary direction by the weight of the body, is torn, and suffers the head of the humerus to escape. This is then placed on the inner edge of the anterior border of the scapula, between the subscapular muscle, which is before, and the long portion of the biceps, which is behind. The pectoralis major and corresponding muscles act like a lever, the point d'appui of which is at the elbow, and the resistance to which is at the shoulder-joint. The luxation downwards may also, according to some authors, be produced by a violent blow on the external part of the shoulder, beneath the acromion. But then it is often complicated with fracture of the scapula or humerus. It may also be caused by mere muscular action in a violent effort of the arm to raise a burden, or in an epileptic fit. The symptoms of this luxation are—lengthening of the arm; its oblique direc-

tion outwards; the elbow separated from the trunk, with inability to approximate it; the head and body bent to the affected side; the fore-arm semiflexed; impossibility of the spontaneous movements of elevation or rotation; pain on attempting these; deformity of the shoulder; projection of the acromion, with a depression under it; a hard round tumor in the axilla.

The luxation inwards or forwards supervenes upon a fall on the elbow, separated from the body, and carried backward. The persistence of this situation when the patient is raised—the presence of a tumor formed by the head of the humerus beneath the clavicle and before the shoulder, which is less deformed than in the preceding case—lastly, the impossibility of bringing the elbow forwards without giving great pain—leave no doubt as to the existence of a luxation of this kind. It is much more rare than dislocation downwards; it is also seldom primary, but almost always consecutive upon the first.

A fall upon the elbow, carried powerfully forward and upwards, may cause dislocation outwards and backwards. This displacement is extremely rare, and would perhaps be impossible, without a vicious disposition of the glenoid cavity; such as its being inclined backwards, and considerably elongated. In this dislocation, the arm, little separated from the breast, is directed forward and inwards—the shoulder is merely flattened at its anterior part—the head of the humerus is driven beneath the spine of the scapula, towards the external border of the anterior angle of this bone.

I have thought it right to enter into these preliminary details, in the first place, particularly with a view to the modifications which I wish to introduce of the theory generally received on this subject, and of which I shall give you a *résumé*. 1st, The elongation of the limb, in the dislocation called *downwards*, is not a fact newly observed. I have seen it in all those whom I have attended during a very long practice. But does this elongation take place in all dislocations of the humerus as some assert; or, on the contrary, is the arm at one time longer, and at another shorter, according to the kind of luxation, as others maintain? 2d, Can the humerus be luxated primitively in one direction only, and are the other varieties only consecutive? 3d, If it be true that there is but one kind of primitive luxation, in what direction is it? 4th, Can dislocation only take place with laceration of the capsular ligament; or is it sufficient that this be stretched and distended? 5th, The capsule being torn, can it, by exercising constriction round the dislocated bone, oppose the reduction, as maintained by Desault; or are we to agree with Astley Cooper, who holds this obstacle to be altogether

imaginary? Lastly, There exist disagreements with regard to the anatomical structure of some of the modes of union of the articulation, each explaining, according to his own views, the mechanism and frequency of dislocation of the humerus. It is thus that some—and I agree with them in opinion—admitting that the lower part of the capsule is most feeble, have considered dislocation downwards as the most common; while others maintain that this part is the thickest, and only rank dislocation downwards in the third degree of frequency. It would be easy for me to adduce facts from my own experience which would settle most of these opinions from henceforward; but I shall confine myself to directing your attention to the various points where cases illustrative of them occur to us. It is generally stated, that luxations of the obicular joints are always *complete*; but pathological anatomy has proved the contrary, by presenting us with incomplete dislocations of the arm and thigh.

Diagnosis between Fracture of the upper end of the Humerus, and Dislocation of the Shoulder.

Every one, continued M. Dupuytren, affected with luxation or fracture of the upper part of the humerus, will be found to have fallen on the side of the injury; but the position of the limb at the moment of falling is not the same in any two cases; and this difference usually decides the kind of lesion which results, and furnishes the means of recognizing it. If—the arm being separated from the body, and carried forwards or outwards with a view to break the fall—there be displacement, then such displacement will be a luxation of the head of the humerus without fracture. If, on the contrary, the arm has been kept close to the side (the patient, for example, having his hand in the pocket of his pantaloon), it is the ball of the shoulder that the weight of the body impinges against, and then, if there be displacement, it is as the result of fracture, or crushing, of the head or the upper part of the humerus. In both cases there is acute pain at the top of the shoulder, and the patient always thinks that the fall has taken place on the seat of his suffering. But when it is the result of luxation, the fall having occurred on the palm of the hand, this last is generally soiled, or bruised and excoriated; if, on the contrary, the pain is caused by fracture, we observe that the fall has taken place on the shoulder itself, by the absence of all marks about the hand, by the soiling of clothes, or even of the skin of the arm, which is also frequently bruised or wounded. In luxation, the pain depends on the laceration of the fibrous capsule and neighbouring tissues; in fracture it results

from the contusion of the upper part of the shoulder and the injury done to the soft parts by the broken bone. There may be ecchymosis about the arm in either case; but in luxation it is produced by laceration about the inner part of the joint, and in fracture by contusion of the outer parts; and thus the seat of such appearance is different, being on the inner side in the former case, and on the outer part of the arm in the latter. Besides, ecchymosis is less common in dislocation, but almost constant in fracture.

In both lesions the acromion is salient, the deltoid flattened; there is a void at its inner margin, and in the hollow of the axilla there is now a projection; but an exact analysis of the symptoms removes the doubts which a superficial examination may have produced. In fact, the projection of the acromion is more considerable, and the flattening of the deltoid greater, in luxation than in fracture, when this muscle appears swollen. In luxation we feel, at the inner side of the deltoid, a very great hollow produced by the displacement of the head of the bone: this hollow is less in fracture. The prominence in the arm-pit in consequence of luxation is very considerable, while in fracture it is much less; and in the former case its shape is round, while it is uneven in the latter. Neither mobility nor crepitation are present in luxation, while they are easily observed in fracture. In short, is the humerus luxated? Motion of the member is vainly attempted, though it may move indeed with the shoulder itself, as if both were one and the same piece. Is it fractured? There is an unnatural mobility on a point in the upper extremity of the bone—a mobility which is usually accompanied by crepitation, perceptible on attempting to rotate the bone about its axis. In fine, what above all other things distinguishes luxation from fracture is, that the former is more difficult of reduction; but once reduced, requires only to have the arm secured to the breast; whilst in fracture an *appareil* is indispensable, in order to keep the fragments in contact, to prevent the muscles from reproducing the displacement, and to obtain a cure without deformity.

It sometimes happens that, when the fracture consists merely in a simple solution of continuity without displacement, it may be confounded with a violent bruise of the shoulder. Our only means of assuring ourselves of what has actually happened, is derived from the diagnosis afforded by crepitation and mobility. We must, however, not let ourselves be deceived by a false crepitation, which consists in the crackling which is sometimes met with, arising from a violent contusion of the shoulder, and which is the result of inflam-

mation of the articular surfaces, and of the want of synovium. The following are some cases calculated to exemplify our views:—

CASE I.—*Fracture of the Neck of the Humerus, with slight Displacement of the Head of the Bone, simulating Luxation.*

An old soldier, at present a shoemaker, aged 62, while walking along an inclined plane received a fall, in which the weight of his body came down upon the left thoracic member. He was taken to the Hôtel Dieu the day after the accident, when there appeared a considerable swelling around the scapulo-humeral articulation; a contraction of the deltoid, with increase of thickness and length of the muscle, which, notwithstanding, was perceptibly pitted; projection of the acromion more marked than usual; inability to bring the arm in contact with the trunk; a crepitation and mobility, though very obscure; a rounded tumor, resembling the head of the humerus, in the arm-pit; and a sort of prominence at the internal part of the shoulder, beneath the pectoralis major. These were complicated symptoms, but M. Dupuytren pronounced without hesitation the existence of a fracture. The apparatus was applied; but two days after the swelling was augmented, and it was perceived in dressing the patient that the deltoid muscle was not so large, thick, or contracted, as it appeared at first; that it could be depressed; that there was a hollow below the acromion, which was itself less prominent than it had been;—in fine, the absence of all mobility, and the presence of a perfectly rounded head in the arm-pit, gave reason to pause before finally adopting the opinion of its being a fracture.

Some attempts were made at extension. A cushion filling the arm-pit was managed as in fracture of the clavicle; the arm applied to the cushion was fixed there by several circular folds of a roller, commencing at the lower part of the limb, and encircling the trunk, and so applied as that the inferior third of the humerus, covered by the roller, was directed a little forwards and inwards, whilst its superior extremity was turned a little backwards and upwards, resting meantime on the cushion. In five days the swelling had subsided and was nearly gone; crepitation was easily discovered, and the fingers introduced into the arm-pit could feel the inferior fragment, which was very rough, and seemed to be composed of several pieces slightly moveable. The head of the humerus could also be felt; it was displaced, and turned a little forwards and inwards. The *appareil* was re-applied, and renewed at first every three days, afterwards every five or six. On the fortieth day it was removed altogether;

there was no more mobility or crepitation; the limb had resumed its ordinary length, and the deltoid and acromion their proper condition.

CASE II.—*Luxation of the Right Humerus upwards and forwards, consecutive on a Luxation inwards.*

Hamlin, 26 years of age, a glass-cutter, was giving help at a fire, and while walking hastily along the roof of a house five stories high, fell into a yard, breaking his fall by striking against a wooden shed eight feet from the ground. Upon reaching the Hôtel Dieu there were found on him a luxation of the humerus, and several grievous bruises. The arm was placed on a pillow, the contusions were fomented, and a bleeding was performed.

Next day, the patient lying on his back, his arm was laid on the pillow at a right angle from his body; the palm of the hand was turned forward, and the whole member was in the most complete state of supination. Upon feeling in the arm-pit, no projection was found; but on moving the finger forward, there was detected within and beneath the pectoral muscles a projection formed by the head of the humerus, separated by only a few lines from the clavicle. By pursuing the examination after this manner, a luxation forwards and upwards, consecutive on a luxation inwards, was readily recognized. The patient was again bled, to produce faintness. On the following day, before the process for reduction was begun, M. Dupuytren observed that it would be probably a laborious business, for they had to deal with a strong man, robust and muscular; and this sort of luxation was attended with much more difficulty than when it was downwards and inwards. This proved to be the case. The reduction was not accomplished until after severe and protracted exertions, and turning off the patient's attention repeatedly by anxious and multiplied questions. The arm was then placed, and kept in a semiflex position, and attached to the trunk by the aid of a towel. Fomentations were applied to the shoulder. In the course of twenty days the patient was allowed to move the parts; but it was long before he could recover the full use of his arm.

Luxation of the humerus is sometimes attended with fracture of the neck of the bone. In such cases, even the combination of nature and the resources of art can avail but little; yet a good diagnosis is of great value, in order to direct the proper applications. In order to distinguish the existence of fracture in such circumstances, M. Dupuytren's rule is this:—Restore to the limb, by suitable methods, its natural form and length; then revisit the patient in about seven or eight hours, and if you

find the shoulder deformed, you may be sure that there is fracture.

We have seen, continued M. Dupuytren, how difficult it sometimes is to distinguish luxation, even when recent, from fracture of the humerus. This, however, ought only to stimulate you to acquire precise notions regarding the nature of such injuries; for mistakes on this head are common only among persons ill-taught, and little accustomed to practice. In this hospital we have often had to treat patients labouring under luxations or fractures, which had been mistaken by practitioners in town, although the characteristic symptoms were quite clear. But in old luxations the distinguishing signs are much more difficult to ascertain. Of this you must be persuaded from the very case which has led to these remarks. The symptoms of fracture, if they ever existed, may have disappeared; there remain, of course, those common to both injuries; but there are, besides, the peculiar symptoms of luxation, which time does not efface. These last it behoves us to make well in precarious instances.

For this purpose we must attend to the diagnostic signs given in the preceding observations, namely—1st, the lengthening of the arm, a sign by no means *new*, as we have already said, but of which hitherto all the importance has not been appreciated; 2d, the lengthening of the anterior limit of the axilla; 3d, the deformity of the shoulder, and the easy pitting of the deltoid under the fingers. As to the projection which is observed in front, beneath the coracoid process, and the pectoralis major, and which is independent of the osseous projection in the axilla, we must not attach more importance to it than it really deserves; for it is likewise observed in cases where the fracture is attended by a slight displacement of the bone.

In the latter part of this lecture M. Dupuytren noticed that subject which may be considered altogether new in his hands, and which nobody, he said, had fully discussed before himself, namely, the question as to how long a period shall have elapsed after the occurrence of a luxation, before we are justified in abandoning its reduction. The difference which exists in the possibility of reduction of fractures is greatly modified by this standing. After several days, the soft parts and the bone have contracted habits of position. The ligaments and muscles surrounding a disturbed articulation acquire a stiffness which does not readily yield to reductive processes; and it may happen that the cicatrices, after the rupture of the orbicular ligaments, may have already rendered the return of the bone into its cavity impossible.

It is only by repeated and multiplied

experience, observed M. Dupuytren, that any approach can be made to the solution of the question. The ancients thought it improper to attempt the reduction of a luxation after it had existed for some days; and this rule of conduct was long prevalent in the medical world. Benjamin Bell professed it, though he was well acquainted with the success which other English surgeons had obtained by contrary practice; his authority, however, influenced even Desault; but if we may believe Bichat, experience soon led Desault to a bolder method of proceeding—in fact, the success which he met with in treating luxations of from fifteen to twenty days standing, led him to try what could be done after five and thirty. Bichat adds, that he has even Desault, in the last two years of his life, reducing luxations of two, three, and even four months' duration.

A memoir, containing six cases, by M. Flaubert, of Rouen, and published in the *Repertoire d'Anatomie et Chirurgie*, would give little encouragement to practitioners desirous of reducing old luxations. In five of the said cases, the attempt at reduction gave rise to some serious accidents—the tearing of a large artery, and nerves, and muscles. These accidents, says M. Flaubert, are the more to be dreaded the longer the luxation has existed, and as it may have been accompanied with more or less swelling, and other inflammatory affections. But Dr. Marx, in the same journal, has treated the subject with his usual ability, and arrives at a conclusion altogether different from that of M. Flaubert. Whence, then, the difference? Is it founded on the age, sex, &c. of the different patients? Is it the different mode of reduction? Not this, certainly, for at Rouen the process is exactly the same as that employed in the *Hôtel Dieu*. The whole difference seems, in short, to be this—that M. Flaubert was unfortunate in his cases; he was more unlucky than other surgeons in the cases which he took for his examples.

Of thirty-three cases of luxation brought forward to support the views of M. Dupuytren, twenty-five are of the shoulder in different directions, five of the femur, and three of the fore-arm; the following is a tabular view of them:—

5	were reduced from the 5th to the 10th day.
6 10th 20th ..
4 20th 30th ..
5 30th 40th ..
5 40th 50th ..
2 50th 60th ..
2 70th 80th ..
2 80th 90th ..
1 90th 100th ..
1 after two years.

Of the last case an account is given in

the Memoirs of the Acad. of Surgery, vol. v.; it was a displacement of the thigh which occurred in the person of a young lady, twenty-two years of age, at the moment of parturition. Forestier, Tissot, and Cabanis of Geneva, saw the case, and recognised the luxation; yet it is but fair to add, that doubts have been entertained by high authorities touching the real nature of the injury.

MIDDLESEX HOSPITAL.

CASES: WITH REMARKS,
BY MR. ARNOTT.

IN the lecture introductory to those which I lately gave on the diseases of the eye, I stated, that the establishment of special institutions for the treatment of those diseases under the care of individuals distinguished for acquirements in general pathology, had no doubt materially contributed to the progress of ophthalmic surgery in England. Our knowledge of the nature and treatment of the morbid affections of the organ of vision was thereby increased, and the attention of the profession at large recalled to a subject which it undoubtedly had neglected.

That the establishment of express institutions for ophthalmic diseases might also, under the formerly existing circumstances, have presented the only means by which this branch could be reunited to general surgery, is possibly true; but it does not appear so clearly to follow that the same means are most likely to render the union either complete or permanent. This cannot be considered as accomplished until the principles and practice of ophthalmic surgery are taught under the same roof as medicine and surgery generally. With this view, and to the more efficient relief of the sick, a small ward should be allotted in each of our large hospitals for the reception of eye cases—for the more severe forms of ophthalmic inflammation, and those requiring operation, which demand protection from light and currents of air in a manner which cannot be effected in the other wards. It would also be advantageous to see out-patients (who form by far the greatest number of applicants), with diseases of the eye, twice or thrice a week. In this way, the great object of these charities would be promoted, with little additional expense, and the surgical instruction rendered more complete.

Situated as we are, opportunities for the observation of diseases of the eye are by no means wanting, and there are at present in the hospital several cases, and others which have recently left, to which I shall now advert.

Catarrho-Rheumatic Ophthalmia.

Mary B. æt. 77, admitted Feb. 19th, 1833, with an ulcer of the leg, which in three weeks had healed, and she was about to be discharged, when, on the 13th of March, she complained of some uneasiness of the left eye, for which a purge and cold lotion were ordered.

16th.—Great redness of the conjunctiva oculi, and in a marked degree of the subjacent sclerotic; slight superficial ulceration on the nasal side of the cornea close to its margin; transparent mucus on the edges of the eyelids, which had been glued together in the morning; much pain in the eye and side of the head during the preceding night; iris unaffected.

Lecches around the eye. Calomel, gr. iii. Opium, gr. ss. 8vis. horis. Emplast. lyttæ nuchæ, h. s. Hot fomentations, taking care to dry the parts well immediately afterwards.

20th.—Redness of sclerotic diminished. Pain of head relieved; increased secretion of opaque mucus from the conjunctiva; mouth tender.

Omit the calomel and opium. Let a solution of nitrate of silver in distilled water, four grains to the ounce, be dropped into the eye once a-day. Let a solution of oxymuriate of mercury, one grain to eight ounces of water, be used tepid as a collyrium.

24th.—Eye greatly improved; ulceration of the cornea diminished in size; redness of the conjunctiva abated; that of sclerotic gone; mouth still sore.

Continue the solution of nitrate of silver. Omit the collyrium, as it seems to irritate.

30th.—Ulceration of cornea healed, and its situation barely perceptible; no redness of conjunctiva.

April 9th.—Dismissed cured.

Catarrho-Rheumatic Ophthalmia.

James L. æt. 38, admitted March 22d, with violent inflammation of the left eye, less severe of the right. Could not bear the light; the attempt to look up immediately followed by a gush of tears. The edges of the eyelids slightly swollen; their inner surface deep red and villous, and presenting streaks of opaque yellowish mucus. The conjunctiva oculi, and front of sclerotic, crowded with vessels of a bright red colour. A narrow rim of superficial ulceration on the nasal side of the cornea; a larger spot and deeper at its lower part. Feels as if sand was in the eye. Inflammation of right eye less severe; no affection of the cornea. Both eyes gummed together of a morning. Does not complain of headache. No fever. Disease of seventeen days standing; thinks it was produced by cold. Has suffered much increase of

pain in the eye from exposure to the fire of his forge, and yesterday a piece of hot metal struck the left eye. Has been freely purged.

V. S. ad $\frac{3}{4}$ xvi. Hirudines xv. oculo sinistro. Cal. gr. ii. Opium, gr. $\frac{1}{4}$, 6tis horis.

23d.—Hirudines xii. Emplast. lyttæ nuchæ. The solution of nitrate of silver, four grains to the ounce of water, to be dropped into both eyes once a-day. The Lotio Plumbi c. Opio to be applied externally by folded cloths. Belladonna to be applied to vicinity of left eye.

25th.—Mouth slightly tender.

Omit the Calomel. Contin. alia. Ol. Ricini $\frac{3}{4}$ i.

27th.—So much better yesterday, that he imprudently got up and walked about the ward for an hour. More redness of left eye.

Hirudines xii. Haust. Sennæ comp. statim, et repetatur post horas sex si opus sit. Cont. Solutio Nit. Argenti, et Lotio Plumbi c. Opio.

28th.—Hydr. Submur. gr. ii. Antimon. Tartarisat, gr. $\frac{1}{4}$, 6tis horis.

April 1st.—Emplast. lyttæ nuchæ.

3d.—Inflammation of left eye greatly abated. Ulceration on nasal side of cornea has healed; that at lower part nearly so. More redness of right eye.

Hirud. octo loc. dext. Capsul. Papav. pro fotu. Contin. Sol. Nitratis Argenti, et Pt. Pil. 6tis horis.

11th.—Redness of the right eye has entirely, and that of the left has nearly disappeared. The ulcerations of the cornea have now been some days entirely cicatrized, with slight opacity remaining. Sees as well with both eyes as ever he did. No adhesion of eyelids in mornings.

Omit the pills. Continue the solution of nitrate of silver once a-day.

Two days after, the man felt so well that he left the hospital.

I have denominated these, cases of catarrho-rheumatic ophthalmia, because in both the conjunctiva and sclerotic were affected, apparently from cold, with increased secretion of mucus from the former membrane. Indeed, taking the character of this secretion in the last case, we might have been justified in calling it puriform ophthalmia. They occurred at a time when the cold east wind suddenly set in after very mild weather previously, and I saw several other cases of catarrhal ophthalmia at the same time. The treatment was similar in both instances; being a combination of depletives and local astringents to the part—a combination which, however incongruous in theory, is found most advantageous in practice, whenever the conjunctiva is acutely inflamed, and its

character as a mucous membrane developed. In many ordinary cases of catarrhal ophthalmia, and where the sclerotic is not involved, you may frequently dispense even with leeches, and commence with the solution of the nitrate at once, taking care first to open the bowels, and giving some mild diaphoretic at the same time. But whenever the redness of the conjunctiva is at all marked, and especially in young people, I usually begin with leeches, and whenever the sclerotic is affected, invariably so; and in the last related case it will be observed, that, from the participation of the sclerotic and cornea in the morbid process, it was judged prudent to premise venesection.

The ulceration of the cornea, in cases of catarrho-rheumatic ophthalmia, is usually very superficial; in fact, it seems generally limited to that of the conjunctiva of the part, and, when taken in time, does not go deeper into the proper substance of the cornea. Hence, also, it is frequently not followed by permanent opacity of the part. I need hardly remark, that the solution of the nitrate of silver was not applied in these two instances with a view to the ulceration of the cornea, but to remedy the affection of the conjunctiva.

But the effect of treatment is not always so soon witnessed, or are the morbid actions so soon remedied, as in the preceding cases. There occur in the eye diseased changes in which the beneficial operation of remedie is slow, and where these changes require not only weeks but months for their removal. An illustration of this is afforded by a patient now in Bird's Ward.

Scrophulous Corneitis of both Eyes.

Martha B. æt. 8, admitted January 8th, 1833. Excessive intolerance of light. Pain on every attempt to open the eyes. Cornea of the left eye every where opaque, so as to conceal the iris entirely from view, and to render it a matter of uncertainty whether the anterior chamber exists or not. A zone of small red vessels in the sclerotic around the edge of the cornea, and in the conjunctiva a number of larger ones, forming at several points fasciculi. The opacity of the cornea, though general, is unequal, being of less density at some places than others. Vision of the eye is lost, perhaps permanently so. The affection of the right eye not so considerable, but still serious: the nebulous opacity of the cornea does not occupy the whole of this membrane, for through some places near its edge the iris can be seen, but the centre is so occupied that the pupil cannot be discovered. The disease had been of four or five months duration, and had arisen without evident cause. There are cicatrices of ulcers in the neck.

It is unnecessary to enter into a detail

of the daily treatment, more than to state, that leeches were applied in the first instance to both eyes, and have since been repeated four times; that a grain of calomel, and subsequently a grain and a half, and one of antimonial powder, were given morning and evening, which was continued uninterruptedly for upwards of two months; that a discharge was established behind the ears by the application of the blistering plaister, and that aperients were occasionally given.

For the first fortnight the girl kept her head buried in the pillow, the intolerance of light was so great; after this she began to look up in the evening. The cloudiness of the cornea of the right eye now lessened, and we were soon able to distinguish the pupil; but it was five weeks before opacity of the cornea in the left eye shewed any evidence of diminution. The cloudiness first lessened towards the margin of the cornea, so as to allow of the iris being seen, and we were enabled to ascertain that the anterior chamber existed. By slow degrees the pupil of this eye also became perceptible. At present, the centre only of the right cornea is occupied by a slight haze. The opacity in the left is more considerable in degree and extent; but even with this eye she is now able to distinguish persons and objects. A very few red vessels are still seen in the sclerotic coat, and both eyes are still exciteable.

The active agent in this case has undoubtedly been the mercury; this has at no time affected the mouth; but when it had been taken for nine weeks, the girl's health appearing to suffer, it was discontinued, and she was put upon quinine, which has restored her health, but without benefitting the affection of the eyes. The calomel has been resumed, with a confident expectation of still further advantage.

The opacity of the cornea in M. B. seems seated in the proper texture of this part, immediately beneath the conjunctiva, and presents a very different appearance to that of the left eye of the nurse's child in Pike's ward, a girl about the same age. In this case, which was one of Serophulous Ophthalmia, there were two vesicles or aphthæ on the cornea, but the proper substance of this membrane was not affected; they left behind a speck of considerable size, involving the conjunctival covering only; this speck had a large red vessel ramifying in it, and proved very rebellious to treatment, so that I even contemplated removing a portion of the latter. Having, however, tried the effect of the ointment of nitrate of silver, four grains to the drachm of ceratum cetacei, every third day, under five applications of this I have been gratified to find the vessel rapidly contracting in size, and the speck lessening.

It is useful to know not only when to interfere actively or perseveringly, but it is important also to distinguish those cases in which our interference is not merely useless, but may be prejudicial.

CONNEXION BETWEEN THE MOTHER AND FŒTUS.

In our article on this subject last week, the sentence (p. 56) "Ruysch also denied the existence of cells," ought to have formed the conclusion of the passage which immediately precedes it, instead of commencing a new one; and that beginning, "Burdach, we may here mention," &c. (p. 59) ought to have stood as an independent paragraph, instead of being appended to the account of the ease at Middlesex Hospital. Some abruptness, if not obscurity, results from the manner in which the above at present stands.

WEEKLY ACCOUNT OF BURIALS,

From BILLS OF MORTALITY, April 16, 1833.

Age and Debility	97	Bowels & Stomach	10
Apoplexy	10	Brain	4
Asthma	46	Lungs and Pleura	15
Cancer	1	Insanity	2

Prevailing wind, S.W.

Weather variable; heavy showers of rain daily. Several peals of thunder on the afternoon of the 11th; and on that of the 15th a fall of snow, the flakes of which were remarkably large. Showers of hail fell on the 11th and 14th.

Rain fallen, .925 of an inch.

CHARLES HENRY ADAMS.

NOTICE.

REB will find the description which he seeks, in the Transactions of the Society of Arts, vol. xlix. part 1.

LECTURES

ON THE

THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE CHEST.

—
BRONCHITIS.

Treatment of the acute form.—In regard to the treatment of this disease I shall not detain you five minutes, for the treatment is perfectly easy. You have only to bleed the patient well, and follow it up by local bleeding; and according to some the latter answers better at the back than at the front. I do not know that this is the case, but some say they have contrasted the two modes—which is more than I have done. I have generally been contented with cupping at the front. Some say there is more advantage from cupping on each side of the spine, and others prefer the root of the lungs and the large vessels. I am quite sure that in this disease you will find mercury of the greatest use, I have had so many cases that have yielded the moment the mouth has become sore. Or if you choose, instead of making the mouth sore, you will derive advantage from the exhibition of tartar emetic in large doses, so as to keep the patient nauseated, and from time to time produce vomiting. Vomiting causes a great discharge from the affected parts, and therefore it is more useful than in any other inflammation. In many inflammations it would be dangerous to practise vomiting; but in bronchitis, many trust, next to bleeding, to the exhibition of full doses of tartar emetic—a grain or more

every three or four hours. However, I am not so satisfied with this plan as with making the mouth sore; but if the patient do not go on so fast as you could wish, then you may give tartar emetic afterwards; nevertheless, I am quite satisfied that making the mouth sore is one of the most expeditious modes of cure. I need not say that blisters, low diet, and moderate purging, are also exceedingly proper. The treatment is that of common inflammation; and if it be well practised in time, and provided the patient be not the subject of chronic bronchitis, the treatment is easy enough. If the patient have acute supervening on chronic disease, your chance is slight; but even then the case must be treated on the same principles.

Asthenic Bronchitis.—Now it is to be remembered particularly, that this disease will sometimes destroy life in the most insidious manner. I mentioned that it will exist without pain, and then it may be easily passed over; and I likewise mentioned that it will frequently exist with little cough—not half the cough that you often have in common catarrh—and then also it may be easily passed over. The patient is considered to have a little cold; but there is such prostration of strength as surprises every body; and in three or four days the individual is past hope. I have known several cases of this description. This occurrence takes place particularly in those advanced in life, and therefore, whenever you are consulted by individuals near 60, or who have passed that age, and you observe difficulty of breathing, the respiration hard, and the pulse quicker than it ought to be, it is well to listen to the chest, and find what disease he has. You may find the respiration to be sonorous, sibilous, or both, or perhaps mucous, and the patient may be labouring under excessive inflammation of the bronchiæ. You may hear these sounds in many parts of the chest.

This species of the affection is called *asthenic bronchitis*—that is, that form of in-

flammation which is described as *atonic*, where the inflammation, however active, may be attended by no great strength of constitution; and it very soon degenerates into passive inflammation, or the patient absolutely sinks. There is no power in the system, but the parts themselves are more or less inflamed; and at that time of life, with such a state of the constitution, the inflammation is sufficient to expend all the powers, and at the end of a few days the patient sinks. It is therefore necessary, when a patient in the decline of life has a cold sufficient to make him call in medical assistance, carefully to examine the breathing, and observe whether it is frequent or not; to listen all over the chest, to ascertain whether there is not a pretty considerable degree of bronchitis—considerable either in degree or extent; for sometimes it is inconsiderable in degree, but considerable in extent, and that is quite sufficient to hurry the respiration.

Treatment.—This is an unpleasant case to treat, and I have lost many such patients in a winter. They are usually 70 years of age, or older; they have bronchitis; they cannot bear much bleeding; their powers are gone; and it is vain frequently to attempt to relieve them. All you can do is to bleed to two ounces, to bleed locally, apply blisters, get the mouth sore, and give emetics; but you cannot do much with any thing. When you hear sonorous and sibilous rattle degenerate into mucous rattle—if this be observed all over the chest—if the patients' powers be gone, and they cannot lift themselves in bed without aid, by good support, by wine and milk, (and some give bark), you will occasionally get them through; but very frequently, in spite of all you can do, they will slip through your fingers. It is always provoking to lose a patient; but there is sometimes an especial reason for it, and you lose your credit because you have not alarmed the family as you should have done. When old people are attacked with this disease in such an insidious manner, and their strength is all gone, it is very easy to offend the family by saying the patient has only a cold, when he is all but dead.

I have heard some old practitioners say that these cases should be treated with bark and wine from the very first, and that they invariably cure the patient. One always doubts a man who says he cures *every* complaint, however excellent his plan may be. The powers have been prostrated from time to time by something or other; but after the first bleeding (perhaps you cannot go far with it), blistering, a slight affection of the mouth, or nausea and vomiting, in a short time it is necessary to support the patient well; and if there be

any doubt about the propriety of going on with this, it is better to do so, and to give an emetic every day, so as to clear out the chest and induce a free secretion, and during the rest of the day to give bark or quinine, and good nourishment, even wine. In these cases it is necessary to procure rest by means of opiates, or narcotics, of various descriptions; but the essential thing is to cure the bronchitis. The bronchitis frequently comes on in an insidious manner, and is accompanied by no constitutional signs, but it is in old people that this particularly happens; we never see it in children, or in the middle period of life, but in those advanced in years we see it every day.

Impropriety of the term Peripneumonia Notha.—It is this form of the disease particularly that has been called *peripneumonia notha*, as if there were bastard peripneumonia, not the real thing; but I believe the word is used very indefinitely. Sydenham applies this expression to common bronchitis, where the head is ready to split, and where all the symptoms present are such as I described as common to bronchitis. We had better abolish the term "*peripneumonia notha*," and remember that there is a disease of the air-tubes—that is, bronchitis, that may be active, accompanied by strength, and must be cured by strong measures; and that sometimes it is attended by no strength at all, or at least the strength will all go in a day or two, and whatever measures are adopted must be employed the first few days. I believe the word "*peripneumonia notha*" was supposed by some to apply to the latter state only; but if you read Sydenham, it is clear he applies the word to those cases where there is considerable pain.

Speaking of the rattles, I should mention, that if the affected part be at a considerable distance from the front, you cannot hear them well; the nearer they are to the surface, the louder you hear them. Sometimes, if you place your hand over the chest, you discover a vibration at the same moment; but that is not always the case. It depends upon the extent, or the intensity, of the affection: if the air pass with great difficulty, it shakes that portion of the chest. However, it is not of very great importance.

CHRONIC BRONCHITIS.

Now bronchitis is very frequently a chronic disease; sometimes, and indeed generally, it is a mere degeneration of the acute form. The disease, when it has once begun, however acute it may be, in some persons never ceases; they have it at least every winter afterwards. I think I mentioned before, that another attack of

the disease may not be active, but more or less passive, and some have the affection for two or three years, and then they die. But if you ask many asthmatic people, as they are called—that is, persons who have passive bronchitis every winter, they will tell you that it came on originally after severe inflammation of the lungs, or a very violent cold.

It is in the middle aged and young that chronic bronchitis is most frequently the consequence of a very acute affection; in old people it generally comes on very slowly, and is the consequence of what is nothing apparently but *catarrh*—that is to say, a very slight acute attack of bronchitis, in old persons, degenerates into chronic bronchitis. In old people, too, it comes on very imperceptibly; they will perhaps have a severe cold one winter, and have it for two or three months, and then the next winter they will have it still worse, and so they go on as long as they live, having it worse and worse every winter.

Frequently considered as Asthma.—Now this chronic bronchitis passes vulgarly under the name of *asthma*; and even among some medical men, especially those educated a long time ago, the term “*asthma*” is applied to bronchitis. Now *asthma* is, properly speaking, a pectoral difficulty of breathing. I say *pectoral*, because the causes of many difficulties of breathing are situated in the windpipe—the larynx. A spasmodic dyspnoea may be situated altogether in the larynx. *Asthma*, however, is purely pectoral. A spasmodic difficulty of breathing, such as true *asthma*, is frequently united with inflammation or congestion of the mucous membrane of the bronchiæ, frequently united with chronic bronchitis; because when the mucous membrane is inflamed, it is commonly thrown into spasm, and unless it be removed the muscles are also thrown into a state of spasm.

Humoral Asthma.—Now when the two diseases are united, they pass under the name of *humoral asthma*—that is, spasmodic difficulty of breathing, with a great quantity of fluids in the chest. The humoral *asthma*, mentioned in old writers, is nothing more than what I have now stated.

Frequently a cause of Asthma.—Chronic bronchitis is very frequently the cause of *asthma*. When a part has been inflamed frequently, it becomes excessively irritable, and at length spasm takes place; so that when a person has chronic bronchitis it is worse at one place than another—it is worse at one season than at another, and the patient will be seized all in a moment with an additional difficulty of breathing. You may have spasm sometimes without any inflammation of the bronchial tubes, but a common cause of spasmodic diffi-

culty of breathing is certainly chronic bronchitis.

Variations in the extent of the expectoration.—Now this chronic bronchitis, whether it is united with a spasmodic condition or not, varies from a great congestion of the bronchial membrane, and of the whole lungs, down to a mere gleet—a mere flux or gleet of the mucous membrane, in which state the mucous membrane may be red, or without the ordinary signs of inflammation. You may have nothing but a mere gleet, such as occurs in gonorrhœa when it has long gone by, and which, of course, does not deserve the name of inflammation. It appears to me, as I mentioned in the introductory lectures, that in the latter case there is exactly the same state as we see in a serous membrane where it pours forth a great quantity of fluid, but you cannot discover signs of inflammation at all; on the contrary, the parts are whiter than usual, having the appearance of satin.

Symptoms.—In all these varieties of chronic bronchitis there is cough, there is copious expectoration, and the expectoration is of all descriptions—frothy, ropy, mucous, serous, watery, tenacious, and viscid, like gluten. Sometimes it is short and creamy, just like pus, and sometimes it is absolutely purulent. These varieties of expectoration frequently co-exist in different proportions, and sometimes they succeed each other. They are sweet, inodorous, or they may be dreadfully fetid; but there is no danger from the latter circumstance. I have seen persons with such a fetid expectoration that their sisters could not bear to sleep with them; and so fetid, that they were disagreeable to themselves, and yet no sign of danger whatever presented itself, and the patients did exceedingly well. They were going about without any particular ailment, except that they had a copious expectoration. In colour it will sometimes be bluish, sometimes black, yellow, green, brown, and even reddish, from having a little blood in it. Then, as to quantity, it may vary from a few ounces to two or three pints in the twenty-four hours. The other symptoms vary in intensity; there may be dyspnoea, or there may be none at all. There may be merely cough and expectoration; but that is more particularly the case in what may be called gleet only of the mucous membrane. When there is congestion of the lungs, or a spasmodic constriction, then you may have difficulty of breathing; and in other cases there may be such dyspnoea that the patient cannot lie down—such dyspnoea, that it will cause plethora of the head, face, and neck, distention of the jugulars, suffusion of the eyes, and I might almost say blackness of the nose and lips, and in some instances even of the whole face.

The extremities in such cases of extreme congestion may become cold and blue, and the urine scanty. The pulse may be either full, or small and feeble. In short, there may be all those symptoms which make many believe that hydro-thorax has existed—that unquestionably there has been water in the chest. It is in cases of this description that we are told every day, by those who never employ their ears, that such a patient has water in the chest, and yet on opening them you find none at all, or not sufficient to explain the symptoms. I have frequently seen persons with all these severe symptoms, and yet, on opening the chest there has not been a drop of water in it, but I have found the lungs so congested with blood that they would not collapse. On listening with the ear, all this was clear before hand. Respiration was heard at the lowest part of the chest; whereas, if water had been there, you could not have heard it. On whatever side water exists, if the person be upright, there can be no respiration in the situation of the water, and on striking the part there can be no hollow sound; on the contrary, it is like striking the thigh. Chronic bronchitis, therefore, may sometimes exist without any congestion of the lungs at all, or there may be the greatest degree of congestion.

Importance of Auscultation.—This disease is very easily recognized, without auscultation; but the simplicity of the affection can only be determined by the aid of the ear. A person may easily say that another has bronchitis, whether it is acute or chronic; but without the aid of the ear it is frequently impossible to say whether there is not something worse than bronchitis. Bronchitis may be frequently cured, or so reduced that little may be left; but there may be another disease present of a fatal character, and you may only be able to ascertain this by the ear.

In chronic bronchitis you may have the rattles of which I spoke in most or nearly all parts of the chest, and they will be in different parts on different days. You may have different rattles on different days—sonorous rattle one day, sibilous another, and mucous another. The mucous rattle is seldom continuous; it generally arises from the presence of a great quantity of mucus, and if patients clear themselves well, as they do, once or twice a-day, then the mucous rattle ceases. In this, as in the acute affection, the respiration may cease occasionally in particular parts. It is by no means so frequently suspended as in the acute form of the disease, and some say that it never is; but occasionally it is lost, and then for the most part you hear it again.

Mistaken for Phthisis.—That form of the disease which is characterised by a great expectoration, and that nearly like pus, attended by a little dyspnoea, but no signs of congestion, and is followed by emaciation, so that people waste, and at last become hectic, is continually mistaken for phthisis; while that, on the other hand, where there is congestion, is mistaken for hydro-thorax. That species which is so often passed by and mistaken for phthisis, may, if properly attended to, often be cured.

This form, indeed, is known best by the general symptoms, rather than by the peculiar symptoms I have already mentioned. It is ascertainable by the ear, and by the absence of other symptoms of phthisis; just as the congestive form of the disease is known, not only by passive symptoms, but by the absence of signs of hydro-thorax—induration of the lung, and complete obstruction of it, the absence of signs of disease of the heart, and so on. This form of the disease is known by the absence of pectoriloquy, and other signs, which I shall hereafter mention.

Catarrhus Senilis—I may state that you will find in authors various names given to this kind of affection. When it occurs in old people it is called *catarrhus senilis*; that is, a kind of bronchitis, attended with various degrees of congestion, and frequently none, but gleet, and a great discharge; and as it occurs in old people it is called “*catarrhus senilis*,” but it is nothing more than an ordinary affection of a mucous membrane, that mucous membrane being the bronchial. Laennec considers it a particular form of chronic bronchitis, which is more frequently attended with asthmatic complaints than any other. He says, that what is called asthmatic spasmodic difficulty of breathing, most frequently arises from a kind of bronchitis in which the secretion is exceedingly viscid; where the mucous membrane is thickened and swelled, particularly in the small branches, so that some of them are nearly blocked up, and where the secretion is glutinous, even firmer than pitch, and disposed to form globules the size of hemp or millet seeds, semi-transparent, and of a pale grey colour. I have no observations of my own on this subject. I have not been able to verify Laennec’s remark; but as he asserts it, it is worth attending to. Where we find asthma occurring, we ought to suspect that it is not a pure disease, but dependent upon bronchitis; and we ought to ascertain whether the expectoration possesses the characters just enumerated. He says, these globular bodies are seen in the expectorated phlegm, and occasionally less consistent, and grow yellow, and sometimes resemble the vitreous humour of the eye.

Such an expectoration is hardly noticed by the patient in the midst of the common mucus which is secreted from the large branches, and gives rise to so slight a cough as not to merit his attention. He says, the difficulty of breathing—the spasmodic ailment, is almost the only thing of which the patient complains.

Here is a third disease, which may be supposed to exist without chronic bronchitis, and has continually been mistaken. Chronic bronchitis, attended by emaciation, may be mistaken for phthisis; where there is great congestion, it may be mistaken for water in the chest; but it appears that that particular form where there is an exceedingly viscid secretion, with small globular bodies, is continually mistaken for pure asthma. This is what Laennec asserts.

Effects of Chronic Bronchitis.

Dilatation of the Bronchial Tubes.—Now, when chronic bronchitis has existed for a length of time, it is very common for something more than congestion, and a thickening of the mucous membrane, to take place—it is very common for the bronchial tubes in the lungs to become dilated. Sometimes one, sometimes several branches, and occasionally the whole of the branches in one lung, will become so large, that those which naturally should admit only a fine probe, will have a canal equal to that of a common goose-quill, or even sufficient to admit a finger; and perhaps these very dilated branches are seen spreading to others nothing like so large as themselves. This is the consequence, in some instances, of chronic bronchitis; but whether it is that the particular tubes become hypertrophied, so as to grow to this diameter—grow, in every sense of the word—or whether they become so distended with mucus that they acquire this increased cavity, I cannot say. It is, however, by no means an uncommon occurrence.

There are two or three varieties of this dilatation. Sometimes you see it throughout the tube, and it may occur in one tube or several; and not unfrequently the coats of the tube are hypertrophied and indurated at the same time. Secondly, the tubes are sometimes only enlarged in one spot, and then a mere cavity exists, which is occasionally so large that it will contain a nut. In a third form, the dilatation will occur at intervals, so that there is a series of small enlargements. The pulmonary texture, on being cut into, appears as if it were swollen with a number of small red tumors, and the whole become filled with a puriform secretion. In this last form the coats are said to be always thin, as though the dilatation had arisen merely from mucus; while, in the two first forms that I

have mentioned, the coats are generally hypertrophied, and the dilatation appears to be the result of the hypertrophy. Hence it would appear, that this dilatation occurs sometimes from hypertrophy, and sometimes from a mere obstruction by mucus; and the result is, that, in two forms of the disease, either the whole length or a part of the tube is dilated, just as is the case sometimes with the heart; and in the third form there is a series like a string of beads, and the coats are exceedingly thin, as though it resulted, not from hypertrophy—for then the parts would not be thinner—but from simple distention. In cases of this description some other symptoms arise. The disease is attended with great debility, and the patient is broken-winded.

Auscultatory Signs.—Now you may suppose that such an alteration as this will give rise to some alteration in the sound of the chest. This is a matter rather of curiosity and of pathology than of practical importance; but still, if any thing produce any symptom whatever, it is right you should know what it is—whether it will turn to good account or not. We ought to make it a general rule to go straight forward, and make as accurate a diagnosis as possible, whether we can do good or not; because, if it be not of practical application to-day, yet it may become so afterwards. We must not despise a discovery because it is not applicable to practice; it is not usual to say, what is the good of this, that, or other, if it be known, till the time comes to turn it to good account?

When small tubes are dilated, they approach nearer to the natural size of large tubes—they approach nearer, of course, to the size of the trachea; and therefore, if there be any difference in the sound of respiration, in the sound of a cough, or in the sound of the voice, in the large branches, it ought to be the same when the small tubes become large ones;—and this is actually the case.

The sound which is commonly heard in respiration in a healthy chest, called “vesicular respiration,” it would be best to learn by listening to the chest of your friends. The ground-work is to be learned by listening to the healthy sounds of the chest; and therefore, without patients, you may learn it of each other. Listen to your friend’s lungs—listen to your friend’s heart—and when you have learned the normal sounds only is it time to learn the unnatural sounds. If you listen to different parts of the chest of an healthy individual, you hear different sounds in respiration. If you listen to the lungs, in general you hear that minute murmuring which is called vesicular respiration, or, by Laennec, the respiratory murmur; but

if you listen over those parts where you know that there are large branches of the bronchiæ, you do not hear that fine murmur, but rather a rougher sound; there is not a distinct murmur, a feeble crepitation, but there is a rough passage of air—such as you may suppose will take place if air be traversing a pretty large tube. When it goes into a vesicle and out again, there is a minute crepitation, scarcely to be called a crepitation, and it gives the sound of murmur; but if you listen over a large tube—the division of the trachea—you hear a rougher sound. This is all I can say—you must listen to understand it. Then, if you listen to the trachea itself, you have a still rougher sound, merely from the tube being so much larger.

The respiration heard in the chest at large is called “vesicular respiration,” because it is the sound of respiration passing to and fro in the air cells. The sound in the bronchiæ is the *bronchial* respiration, and that in the trachea, the *tracheal* respiration.

Tracheal Respiration.—You will hear tracheal respiration at the anterior and lateral parts of the neck; you will hear it at the upper part of the sternum—the superior sternal region; you will also hear it at the superior portion of the infra clavicular regions, just under the clavicle; and you will hear it at the cervical portions of the acromion region, near the acromion of the scapula. In these situations you hear the sounds of respiration which the trachea gives.

Bronchial Respiration.—Then you hear the sound which the large branches of the bronchiæ give, what is called bronchial respiration, in the middle sternal region—that is to say, below the part of which I have just spoken; and you will hear it to the right and left of it. Here you will hear bronchial respiration—the sound of air traversing the large bronchiæ; and you will hear it in persons, if they be thin, between the scapulæ and in the axilla.

Vesicular Respiration.—You will hear the sound of air in passing to and fro in the air cells—vesicular respiration—in every part excepting the superior and middle portions of the sternum, and to the right and left of these in the axilla, between the acromia, between the scapulæ, between the acromia and the neck, and the superior part of the chest, immediately below the clavicle. It is well to study this from each other.

Alterations in Respiration, produced by dilatation of the Bronchiæ.—If it so happen that certain tubes are dilated, then you will hear, instead of the respiratory murmur which I mentioned, a sound approaching to that of the bronchiæ, and even approaching to that of the trachea. This is

one of the chief signs of the bronchiæ being dilated. They may, as I have just said, be dilated to such an extent as to sound very much like the trachea, but in general you have only bronchial respiration.

If you make the patient speak, and listen to different parts of the chest, you will have very different sounds, according to the part at which you listen. If you listen to the greater part of the chest, you hear nothing particular, but if you listen at those parts where bronchial respiration is heard—that is to say, at the superior part of the sternum, immediately below the clavicle, and also between the scapulæ, you will hear the voice resound very much; you will hear it re-echo; and there is no better mode of expressing it than that. You hear a sound of considerable force, but you hear no such thing if you listen to other parts of the chest. This arises from these parts being situated over the bronchiæ. If you listen over the trachea, you have a loud sound; indeed you hear the voice rush through the tube, so that you have *brongophony*, and what is called *pectoriloquy*. You may have an idea of what is meant by pectoriloquy by passing the stethoscope over the trachea or larynx of any adult person: you find the voice come through the tube to the ear as if the voice were against the ear. The natural sound of the voice below the clavicle, at the upper part of the sternum, and between the scapulæ, is called *agophony*; and the natural sound on the larynx is called *larungephony*.

Now if any of these tubes be very much dilated, if small tubes attain the size of large ones, you will have a sound just as you should over the latter in health—you have brongophony at a part where it should not exist; and if the bronchial tube be dilated enormously, nearly to the size of the trachea, so that it amounts to a cavity, you will have the voice come through the tube into the hear—you will have pectoriloquy; and pectoriloquy is neither more nor less than the same sound that you always hear if you apply the stethoscope to the larynx. It must be a very extreme dilatation, however, for you to hear the voice come through the tube in this way. It is common to have such a sound as you hear in the bronchiæ, but to have such a sound as you hear in the larynx is a rare thing: indeed, there must be a larger dilatation than I ever met with. Such a dilatation occurs from time to time, but it is so rare that I never saw it. There are drawings of it, and there is no doubt as to the existence of the fact. There is, therefore, in dilatation, bronchial respiration and brongophony; and if the latter be very great, there is tracheal re-

spiration and a tracheal voice. As you may suppose, the nearer the tube is to the surface the more clear are these sounds.

Diminution of the Bronchial Tubes.—Chronic bronchitis, however, will sometimes induce the very opposite state: instead of causing the tubes to become dilated, they will become thicker, and the canal be diminished, not dilated. Sometimes there is lymph effused within, so that they are completely obstructed. When lymph has been effused within, and the tube has been obliterated for the time, it has been called a *bronchial polypus*. It is nothing more than the same occurrence that takes place in croup—that is to say, lymph is effused, only not in a tubular form. I once knew a case of gonorrhœa which filled the urethra with lymph, and it was discharged in this way. Where the bronchiæ have been obstructed by lymph, it has been an instance of chronic inflammation—at any rate, not of acute.

In old books you will find it said, that nobody could imagine what was the matter with the patient, and then such a mass as this has been spit up. In cases of this kind you could tell what would be the auricular symptoms. At that part there would be no respiration, and as soon as it was spit up there would be the murmur again.

But without such a cause of obstruction as this, the tubes are sometimes blocked up: the cavity is obliterated by the sides becoming thickened and contracted, and then no respiration, of course, is heard at the part, and this want of respiratory murmur is permanent. In the case of acute bronchitis, it will cease from a momentary obstruction of the tube, for a few hours, but coughing removes it, and you hear it again; but when the obstruction arises from a contraction of the tubes, the want of respiration is permanent.

Dilatation of the Air Cells, improperly termed Emphysema.—Chronic bronchitis produces a change farther, and precisely of the nature of dilatation, of which I have already spoken. The minute tubes of the bronchiæ terminate, as you know, in the air cells, and it occasionally happens that the air cells are dilated by this disease. This has been called *emphysema* of the lungs; but I think it an improper expression, because by *emphysema* we mean the presence of air in the cellular membrane, where there ought to be no air. Now in this case there is no air in the cellular membrane, no air in any place but where it ought to be; only the part which contains the air is too large—contains too much.

These dilated air cells attain, in general,

only the size of millet-seeds; but here and there one may be seen the size of a hemp-seed, and even as large as a cherry-stone.

When they are the size of cherry-stones it is very probable that the air tubes open into the cells, and, all the cells separating from the tubes, they are dilated into one common cavity. I should think this was the cause. You are acquainted with the anatomy of the air tubes and air cells, and therefore are aware, that at the termination of each twig of the bronchiæ, where it is as fine as a hair, the air cells are situated all along it, just like fruit upon a stalk. I think it probable that when a bronchial twig is dilated to a great size the air cells which separate from it are dilated into one.

Occasionally, those of the greatest magnitude actually project on the surface of the lung, and are so prominent as to present a large globular form externally. Sometimes they are as large as a walnut, and even larger. There is a preparation at St. Thomas's (but I suppose we have not one here), where there is a tumor of this description on the surface of the lung. In extreme cases of this description you will see the edge of the lung quite translucent, and standing away from the body of the lung.

If the quantity of air be very considerable, the sides of the cells may crack, and then a communication is established between them and the cellular membrane, so that true *emphysema* is superadded; and in that case the tumor upon the surface of the lung may attain a very great size, and the air may, by pressure, be forced about. Still it is found, notwithstanding that the cells occasionally crack and air escapes into the cellular membrane of the lung, that it does not move about very extensively—not so extensively as it does in other parts of the body.

If lungs with dilated air cells be inflated and then cut into (which I imagine is the best way of preserving them—dilate the lungs, keep them dilated, dry them, and then cut them), the dilatation of particular air cells proves to be more considerable than appeared externally. When the dilatation is considerable, and at the same time so extensive as to occupy the whole lung, instead of collapsing, you will find, on opening the chest, that it rebounds and projects beyond the chest. A lung thus affected necessarily sinks less in water than a healthy lung, and on handling it it does not crepitate in the usual way, but it gives such a sound as would arise from the slow escape of air, and you cannot empty it as readily as you would a healthy lung.

You will find that the tissue of the lung is drier than in health, and even the roots of the lungs have not the usual in-

filtration found in that part. The lungs more resemble those of a reptile than a man. You know what the lung of a frog is; and the human lung is reduced very much to that state. The lung of a frog has a large receptacle for air, not the minute cells that we have; and on opening it, it escapes the boundary of the chest. When only one lung is thus affected, it has been seen to become so much more bulky than the other as to push aside the mediastinum and heart (if on the left side), and produce an enlargement on the right side. Laennec has described this condition of the lungs far more accurately, and far more minutely, than any of his predecessors; but, as you may see from his engravings, it was well known to Dr. Baillie. Dr. Baillie speaks of an enlargement of the air cells causing the lungs to resemble those of amphibious animals. He considers it probable that two or three cells may be broken into one; and therefore, although Laennec has the credit of having first described it, it is right that we should give Dr. Baillie his due. Dr. Baillie also remarks that Sir John Floyer distinctly describes the disease, as seen by him in a mare; and he considers the remark as applicable to the human subject. "The bladders," says Sir John Floyer, "are either broken, and admit the air into the membranous interstices, or else they are over-distended, like a hernia in the peritoneum; and this will produce an inflation of the whole substance of the lungs, and that a continual compression of the air and blood-vessels, which will produce a constant asthma." He was aware of this condition, and he describes asthma as occasionally caused by this over distention.

Causes.—The causes of this over distention, and the still more intense circumstance of the rupture of the coats of the air cells, may be a violent inspiration and retention of the breath, such as occurs in blowing a wind instrument; it may be a mere debility of structure, a loss of elasticity; but the most common cause is occasioned by the want of a due expansion of the lungs. Whatever prevents any one part of the lungs from expanding when the thorax expands—whether it be a material obstruction of the bronchial ramifications, or a compression of them, or whatever else—it will occasion those parts which remain dilatate, to keep dilated in a corresponding increased degree, in order to fill up the vacuum which the expansion of the chest occasions. When we inspire, we dilate the chest, and the air rushes down the trachea, and the lungs follow the dilated portions. If there be any part that will not dilate, then I presume other parts are over dilated, to fill up the vacuum; and

in that way those parts which we distend are over distended, to compensate for the want of distention in other parts; and when once over distended, they are often unable to recover themselves, just as is the case in other parts of the body—the urinary bladder, for instance. I presume it is on this account that the dilatation of the air cells is so common in persons labouring under chronic bronchitis, especially where the membrane is most thickened, and where the secretion, if there be any, is tough and adherent, producing obstruction. Such, at least, is the explanation which presents itself to my mind. Laennec gives, however, a different assumption; he supposes that the air which passes through the imperfectly obstructed tubes in chronic bronchitis, cannot easily escape again, but there it remains imprisoned in the air cells by a mechanism somewhat similar to the mechanism of the valves of an air gun, and the succeeding inspiration introduces a fresh supply, so that the accumulation is very great. I cannot refute this explanation; but the occurrence of the facts upon which I ground my explanation is indisputable, namely, that in inspiration we dilate the chest, and the lungs follow; if one part be obstructed—cannot dilate, the other parts attempt to get more of the air, for the purpose of filling up the cavity of the thorax. Thus when one part is obstructed, another will become dilated; and Laennec, to prove his opinion right, should have shewn that the dilated air cells are those belonging to the tubes in which obstruction exists. That he has not done. I conceive they are not those in which there is obstruction; but, to prove his opinion correct, he should have shewn that the dilated cells belong to the obstructed tubes.

Auscultatory signs.—Now the existence of this state of the lungs—morbid dilatation of the air cells—cannot be known without the use of the ear. Dr. Baillie, of course, knew nothing of auscultation; it was not known or practised till after his time; but he says, with great truth, that when the air cells of the lungs are much enlarged in size, persons have been remarked to have been long subject to difficulty of breathing, more especially on motion of the body; but I believe there are no symptoms at present known by which this disease may be discriminated from some others incidental to the chest. The dyspnoea does not differ from the same symptom under other circumstances; it frequently occurs in paroxysms, and will continue for many years. But the pathognomonic signs are obtained from percussion and auscultation—not from either alone, but from the union of the two; for if, when the air cells

are greatly dilated, you strike that part of the chest, a sound is heard exactly as in health, and perhaps even clearer: from there being but little pulmonary substance there, you have a sound more hollow than even in health. This is the first thing that you must expect; then, if you listen to respiration at the part, there is very little murmur audible. Instead of a number of minute cells, with air rustling in them, there are only two or three cells largely dilated, and therefore the air cannot rustle as before; you hear very little of the respiratory murmur. The air which is there scarcely leaves the air cells—scarcely passes to and fro; the part is not expanded, and the consequence is, that there is very little motion of the air. But it is to be remembered that you do hear some respiratory murmur; and this is the distinction between the presence of air in the pleura and the presence of air in merely dilated air cells. If air exist in the pleura, there it remains; you have a more hollow sound than usual; but on listening there is no respiratory murmur—the air is in a state of stagnation. In the case of dilated air cells, however, there is a little driven out, and a little drawn back again, and therefore there is a trifling respiratory murmur. In the one case there is none, but in the other there is some.

It is said that when this affection is extensive, there is another pathognomonic sign—the inspiration is made with a crackling sound, as if the air were entering and distending lungs which had been dried, and the cells of which had been universally dilated. The lungs are drier in this state than in health, and when the case is very severe the inspirations are attended with the sound I have just described, a sound similar to that produced by blowing into a dry bladder; and this has been termed by Laennec *dry crepitous rattle, with large bubbles*. It is an odd name, but it gives you the idea of dryness, and therefore it is “dry crepitous rattle;” and it gives you the idea of air entering a bladder, and therefore he says, “with large bubbles.” These are extreme cases, and I have never witnessed one of them. If you reflect a moment you will find no difficulty in remembering this. When the tubes are dilated, they approach to the size of the bronchiæ, and you must have the same sound that you hear there; and if the air cells be dilated, it stands to reason that you cannot have the same minute murmur that you have when it is passing a thousand minute cells; and it stands to reason also, that you will have a clear sound there, just as you have in health, because there is air there, as before; and if the dilatation be very considerable, you will have a clearer sound than before, because there is little

else there but air—little pulmonary substance.

Treatment.—I need not say that nothing can be done, either for tubes or air cells that have fallen into this state.

Treatment of Chronic Bronchitis.—With regard to the treatment of chronic bronchitis, it is very various under different circumstances. Accordingly as the symptoms are inflammatory, and your patient strong, must your treatment approach to that for the acute disease; and accordingly as the patient is weak, and there are signs of passive rather than of active inflammation, so must you be careful in lowering the strength. In the latter case, when there are signs of congestion rather than of inflammation, and the powers of the patient are feeble, you may very easily conceive the great importance of not taking away a drop more blood than is absolutely necessary. Where you see the face black, the body bloated, the legs swollen, and a small quantity of urine only is formed, it may be necessary to take away a small quantity of blood, perhaps a little from the jugular vein; or you may cup the patient between the scapulae, and on the front of the chest; but more than a few ounces can seldom be borne. Diuretics and emetics are of the greatest utility. By diuretics you unload the lungs considerably. There is always a great collection of serous fluid in the air cells and tubes, and by diuretics you produce a great alleviation to the patient. It is a good practice to combine digitalis and squills together; you may give many diuretics together, when you cannot increase any one of them. When you cannot give the patient a larger dose of squills without making him sick, you may add digitalis. It is certainly a very common thing for you to be able to give diuretics together, many of which have a tendency to produce sickness, without producing more sickness by the combination of the whole than if you gave only one of them. The efficacy of a diuretic is generally thought to be much increased by giving a small quantity of mercury. This is an old remark, and I believe it is a correct one; you find it stated, that diuretics act more powerfully on the kidneys, if you give a small quantity of mercury with them, than if the latter be omitted.

You will also find great relief from the exhibition of emetics; and among the best is ipecacuanha. If you give antimony two or three times every day, you debilitate the patient; and this is not a case for diminishing the strength. You only want to unload the patient, but antimony is a very depressing agent, and if given every day for a fortnight or three weeks, you may produce great irritation of the mucous membrane of the stomach—gastrodynia;

and therefore I think ipecacuanha is the best. Patients will bear not merely fifteen or twenty grains, but thirty; and it is a safe medicine. I am told that if you give a large quantity, it comes from the stomach, and produces no more effect than a small one. It is of great use to give an emetic every morning, or every other morning, and clear out the bronchiæ; it is an excellent remedy. When acute bronchitis has lasted any time, and you do not think proper to evacuate, emetics may be repeated more freely, especially in the case of children. When the case is not very severe, a nauseating dose of ipecacuanha, squills, and other things of that description, is very useful. Among the best expectorants are those which excite nausea. It is always, of course, necessary to attend to the bowels; if you do not, there is still more congestion; but it is very dangerous to purge briskly. In these cases the powers of the patient soon sink; and it is better to trust to emetics and diuretics.

It is frequently of very great use to blister the chest; but the employment of tartar emetic ointment is rather a severe and cruel mode; and I have not seen that it is any better than an ordinary blister. Some persons are fond of dry cupping; there is no loss of blood, and yet a great determination of it from the inner parts.

Besides remedies of this description, it is frequently necessary to employ others of a soothing nature. Among the best is hyoscyamus, or conium, which may be given night and morning. There is no rule for the dose of these; but you find you may increase them to a much larger quantity than you begin with. I have seldom found stramonium of much use in lessening the cough; it is not to be compared with hyoscyamus, or conium, or opium. Opium is one of the best things, but in many of these cases there is a great disposition to heaviness of the head, and opium has the inconvenience of confining the bowels; so that though it is a good medicine in the form of Dover's powders, yet it is not so good as hemlock or henbane.

You will soothe the air passages much by making a patient inhale different things. They may inhale the steam of hot water; but one of the best modes is not to let them inhale the steam, but have a vessel, and let the air they breathe come through the hot water. You cannot charge air with a dose of salts, but there are many things which may be taken up by the air, and which may be inspired in this way. You might make a solution of opium, or an extract of conium, and let the patient breathe through it. I have not much experience of it, but I have put hyoscyamus and conium into water, and let the patients breathe through it, and with

great relief. Some persons have used prussic acid, and they say that has afforded them great relief. Chlorine may be introduced this way; I have seen it lessen the irritation. Some persons employ iodine; but it is right not to put more than one drop of the saturated solution of iodine. Some patients will bear three or four drops, but some will not bear more than one; and I have known some people who could not bear one drop put into three quarters of a pint of water. It is right to begin with the smallest quantity, and never increase it beyond what is borne without the least irritation. I have a patient at this moment in St. Thomas's, labouring under chronic bronchitis, and who has found great relief from breathing through tanners' liquid. He is taking no medicine, but he says the tanners' liquid has diminished his cough, and he is much better. People living in the neighbourhood of tanners' pits often find their respiration improved.

You will find another description of medicine often useful. Where there is no fulness of the chest, but the bronchitis resembles phthisis—where the patient wastes away, and has a tiresome cough, you will find tonics of great advantage. Where there is a disposition to dropsy, emetics and diuretics are proper; but where the patient is more or less hectic, and is spitting up a great quantity—a state which often occurs in young persons—you find tonics of great use; and you find iron one of the best. There is an interesting case in the first volume of the *Medico-Chirurgical Transactions*, of a young lady supposed to be in a consumption, but by means of three grains of sulphate of iron taken twice a day, she got well. I have had cases of that description without end, where persons were supposed to be on the verge of phthisis, but where there was nothing but bronchitis—no signs of tuberculation, but irritation of the membrane, producing everlasting tickling in the throat.

In those cases where there is a dilatation of the bronchiæ, or of the air cells, the treatment will not vary; you must treat the case on general principles.

SEVERE CASE OF LOW FEVER.

To the Editor of the Medical Gazette.

SIR,

If you should be of opinion that the following communication illustrates very strikingly what is to be obtained from

exertion and perseverance, I should feel much obliged by your giving it a place.

I was requested to visit a boy betwixt six and seven years of age, on the 16th September. He had been complaining for two or three days before; and my partner, Mr. Moir, finding him labouring under symptoms of fever, prescribed an emetic, with a subsequent purge. He was seen again two days after, when the feverish symptoms being still present, it was concluded that the case would terminate in a continued fever, rather of a bilious character, as it could be traced to the eating of a richer diet than usual, and his having eaten a considerable quantity of wild fruit.

It seems quite unnecessary to give a detailed account of the progress of the fever, as there were no local symptoms of any kind (excepting during the first few days a pretty severe and constant headache, which was relieved by the application of leeches); the fever was treated according to circumstances, but in place of obtaining a favourable crisis from the 11th to the 14th day of the fever, the debility rapidly increased, and from the very great difficulty of introducing nourishment, his situation by the 15th or 16th day of the attack became highly dangerous. The pulse was now from 130 to 140, small and indistinct; the features much collapsed; tongue and mouth foul, but neither parched nor black; the emaciation considerable; voiding urine and faeces involuntarily; the feet and body having a great tendency to become cold; the transparent cornea becoming dim and glazed, and appearing insensible to every thing passing around him.

In these desperate circumstances, with no prospect of being able to introduce the necessary support and cordials by the mouth, my sole hope lay in being able to throw them up by the rectum. I accordingly directed an enema, composed of half an English pint of asses' milk, thickened with wheaten flour, and a dessert spoonful of brandy added to them, to be thrown up every eight hours. This was on the 30th of September, the 16th day from the commencement of the fever; and on my visit the next day, I found that the whole of the three enemas had been retained, and there was a slight improvement in the condition of our patient. His pulse, although much the same in

frequency, had a fuller and more distinct throb; had been more quiet and comfortable, evidently sleeping at intervals, which he had not done during the whole of the former part of his fever. The clysters were ordered to be continued, but if possible to procure an evacuation of the bowels before the repetition of every third enema, if necessary; and this by an aperient enema, or by using a piece of soap. Next day I found matters evidently improved; pulse 115, and evidently stronger and more distinct; the glaziness of the cornea gone; enjoying short sleeps, and altogether more comfortable, but still passing stools and urine insensibly. No improvement in his countenance, and the debility and emaciation still increasing; the difficulty of taking food so much increased as to render it extremely doubtful if a drop of any thing is swallowed. The same treatment to be continued.*

On the following day, viz. the 3d of October, matters were at a stand, or rather retrograde; the pulse 125, and not so distinct; emaciation evidently going on, and features more collapsed; still passing urine and faeces insensibly. The clysters since yesterday had only been retained for an hour or two, and not a drop got down by the mouth.

I now endeavoured to examine as perfectly as possible the state of the mouth and throat, and by using some force, I saw that the tongue and mouth were completely aphthous, and concluded that the fauces and gullet were in all probability in the same state. Also, upon examining the points upon which the body rested, I found a dark brown spot about the size of a shilling, notwithstanding every attention had been paid to the changing of his positions. I now ordered a strong dose of cinch. flava, with the addition of nitric acid, and an infusion of capsicum annuum, to be injected into the mouth every four hours, with a syringe, and if possible, to get some of it swallowed. The enemas were ordered to be continued, but every alternate one to be of very strong beef tea, with six drops trœ. opii in each.

At my visit next day I found matters exactly stationary, but the tongue and mouth much improved, and the clysters much longer retained; not at all satisfied that a drop of any thing had yet reached the stomach. Next day things were evidently worse; the debility and

emaciation extreme; pulse both increased in frequency and debility, and not a drop swallowed, although, as far as could be seen, the mouth and fauces were quite clean. I was now satisfied that, unless nourishment could be introduced into the stomach, the case must soon terminate fatally, and that I could not trust any longer to the detergent decoction making its way to the stomach. I immediately determined to introduce the tube of the stomach-pump, and by that means convey nourishment into the stomach. I was, however, very obligingly supplied by Mr. Alexander, a medical practitioner in the neighbourhood, with a more convenient instrument for my purpose, viz. an elastic bottle, which could contain about four ounces, with a very convenient tube. With this machine was introduced, twice or thrice every twenty-four hours, four ounces of strong beef or chicken tea, mixed with arrow root, and a large tea spoonful of brandy added to each; and being convinced that the aphthous ulceration having extended down the œsophagus must be the cause of nothing reaching the stomach, I directed that the point and the whole length of the tube should be wet with the detergent decoction, and alternately rubbed with a detergent linctus, every time the injections were employed.

At my visit on the 9th of October, matters were in every way very much improved, pulse being down to 100, and a good throb. Our little patient was evidently sensible of those around him, but not able to speak, and, for the first time these three weeks, began to swallow in small quantities; but in the appearance of his countenance and body the emaciation going on, and seeming now at its most extreme point, for both the features and body appeared quite horrific, presenting the semblance of a most perfect skeleton.

16th.—In consequence of his swallowing readily, the injections were discontinued, but the enemas were still had recourse to twice a day. But what still excited very great apprehension for the termination of the case, was constant twitching of the muscles of the arms, and even the lower extremities, accompanied every six or eight hours with slight convulsive agitations of the whole body for the space of a minute or two, and these ushered in with evident coldness of the surface, and attended all the

time with loud crying and incessant incoherent vociferation, exciting some apprehension for the state of the brain. It was exactly three weeks since he had spoken a word, and now when speech returned, it was only vociferating a single word. The different brown spots were now scaling off, and he was also capable of motion and the use of his arms. In these circumstances the enemas were discontinued, and calves' feet jelly, good beef tea and chicken broth, thickened with bread, were ordered, but more especially to have the juice of half a pound of beef steak, rather under done, properly obtained by expression, with bread dipt in it, every four or six hours. This last kind of nourishment he highly relished, and took most readily in great quantity.

At my visit on the 18th of October, I was disappointed in finding matters had rather retrograded than improved, pulse being 110, emaciation the same, notwithstanding the quantity of nourishment he had swallowed, and no improvement in the nervous and convulsive motions, or in the incoherent vociferation. This stationary condition I hoped was entirely to be attributed to a total want of sleep, and constant agitation and restlessness; and in order to overcome these distressing circumstances, I again returned to the enemas with laudanum, and also opiates by the mouth; and by making some regulations in his food, and keeping the belly steadily open, a progressive amendment followed; and by the 24th October nothing more was wanting to pronounce him convalescent than the cessation of the incoherent vociferation, which I flattered myself would also cease, as soon as natural sleep returned, and additional strength obtained. Accordingly, on the 3d November I was able to pronounce him convalescent in every respect, which was more than seven weeks from our first attendance, and eight weeks from the commencement of the fever.

Before closing this detail, it may be proper to state, that the place of our patient's residence was three miles distance from Musselburgh; that he was visited during the critical periods of his illness, by Mr. Moir or myself, thrice every day, and we also had the advantage of the occasional assistance of Mr. Alexander for throwing the injections into the stomach, and any other aid which might be required; and sick nurses, with other

attendants, and every thing that was deemed requisite for the successful management of the case, were amply, cheerfully, and readily supplied, by the very anxious and attentive parents; and nearly four bottles of the very best brandy, exclusive of wine, were consumed during the struggle.

Observations.—I have now been extensively engaged in the practice of medicine forty-five years, and during the whole of my experience I have never met with any case of fever, of any description, where no organic lesion existed, and a recovery took place, where there were so many, or rather all the proofs of the most extreme debility and exhaustion present, and also where it was necessary to continue and vary the means considered the most proper to conquer such exhaustion, for so great a length of time.

The first practice which forms a prominent feature in the successful treatment of this case, is that of enemata. It is now forty years since I have been in the regular habit of employing them in combating all cases of temporary debility, where the stomach was either not able to receive, or not capable of digesting, the quantity of food necessary for carrying on the vigour and energy of the system, to the period when a successful crisis might be expected. The good effects to be obtained from this practice were forcibly suggested to my apprehension, both from the capacity and situation of the colon in the abdominal cavity, and also from the very evident proof of the most extensive absorption going on in the fluid matter of the intestinal canal, after reaching that portion of it. From the most extensive experience in this practice, I conclude, that if nourishing and stimulant enemata, or whatever the quality they possess, are retained eight hours, very nearly the same effects will be obtained as from one-half of the quantity given by the mouth, and the whole contents of the enema will have disappeared, as is proved by the next evacuation of the bowels.

With regard to the materials used for the enemata in this case, there is nothing particularly novel in them except the asses' milk; but as the gentleman was in possession of a good milch ass, I had this quite within my reach; and for a period of eight days there was no variation;

and an English pint and a half, mixed as has been previously stated, was regularly thrown up every twenty-four hours. The alternate use of a strong decoction of beef, however, seemed to possess a greater power in raising the pulse; and when they began to be only retained for two or three hours, the addition of the opiate successfully allayed any irritation, and they were again kept as long as could be wished.

It is evident that this practice must be particularly beneficial in all cases of fever, more especially of typhus, scarlatina, cholera maligna, and in all cases of debility where the stomach rejects food, and particularly that vomiting consequent upon weaning. It was from the conviction of the great benefits to be obtained from this practice, that I contrived and had made, by Mr. Millar, optician in Edinburgh, assisted by the late Messrs. Booss, *forty years ago*, a brass syringe containing about two ounces, which worked with valves of a particular construction, and to which were affixed tubes of the very same dimensions, but not of such proper materials, as those now in use, and the whole mode of giving the enema managed in the same way. I also had a tube to attach to the same instrument, for throwing liquids into the stomach, made by the Messrs. Booss; but it was of such coarse and imperfect materials, and rather too short, that I never used it. The whole of the machine is still in my possession, and may be seen by any gentleman who may wish to satisfy himself. When I had the instrument made, I forwarded it to the late Dr. Monro, who returned it with a note saying that he thought the syringe with stop-cock was preferable—an opinion which the present practice in giving enemata pronounces glaringly erroneous; but which, even as applicable to a stomach-pump, is also a mistake, because in using that machine with stop-cocks there is much delay, and may be both confusion and mistake; whereas, in using one working with valves, you may first throw in any quantity of liquid you please, and by merely changing the connexion of the tubes with the syringe you may exhaust the whole contents of the stomach without the smallest interruption. I was led to the contrivance of this instrument from a peculiar case of ileus, which I published in the Medical Commentaries about the period I have al-

ready mentioned, and wherein it is characterized by the late Dr. Duncan's father, as "an instrument properly contrived for the purpose." The late Dr. Lata also borrowed it from me, in order to have one made like it, from seeing it used in a case of hernia. I trust you will excuse my being so particular in this matter; but I think it only justice to state these facts, merely to shew there is nothing so very new either in the stomach pump or enema machines.

Notwithstanding, however, the steady and extensive use of the enemas, it appears from the foregoing detail that we must have lost our little patient, as they were found to be quite inadequate even to check completely, far less procure an abatement of the emaciation; and unless measures of the kind already described had been resorted to, to convey nourishment by the mouth, the supply necessary for the restoration of health and vigour must have failed; and from the use of the bottle and tube, as already described, means were also found to remove the aphthous ulceration of the throat and gullet, whereby he soon began to swallow readily, so that by the fourth or fifth day the use of the injecting machine was no longer necessary. It may be here remarked, that before swallowing food naturally, both the nourishing enemas and the injections were requisite to keep him from sinking; but as soon as that was effected, the enemas alone were used, and they also were abandoned in five or six days more, when the quantity of food taken by the mouth was both ample and nutritious.

I cannot close my observations without noticing the signal benefit derived from the juice of the beef steak. This is an article of nourishment which I have now for many years been in the habit of prescribing in cases of debility of habit, accompanied with no desire for food. It is peculiarly grateful, and much nourishment is contained in comparatively little bulk, and it is almost universally liked. I have received the most striking benefit from the beef juice where debility occurs in children, and very remarkably so in cases of whooping cough of the most desperate character, where all the bland articles of nourishment, even including an abundant supply of asses' milk, failed, and the case was rapidly progressing to a fatal termination. Indeed, so firmly am I

satisfied of the great importance of this change in the diet, that wherever the usual practice has been fairly tried, and the symptoms of debility are becoming alarming, it should be instantly had recourse to, and the best effects will be very soon found to follow. My theory for the good effects of this practice is, that the usual ingesta in whooping cough are all of a liquid, bland, and bulky nature, and possess no grateful or stimulating quality, so as to induce its quick digestion, but create much difficulty of breathing and increased coughing, by distending the stomach; whereas, the beef steak juice is the very reverse, and from its nutritious and grateful qualities a beneficial effect is rapidly obtained.

These last observations naturally lead me to notice another important point of practice in fevers, which was very distinctly marked here, viz. that when the period of the fever arrived at which I judged it necessary to allow wine, I began with the use of sherry, when considerable flatulence and distention of the stomach and bowels became troublesome, from being attended with great uneasiness and griping. It was no better in trying the use of port; but on employing the brandy, these inconvenient and troublesome symptoms entirely disappeared.

I am, sir,
Your obedient servant,
THOMAS BROWN,
Musselburgh.

April 4, 1833.

CASES OF EYE DISEASES; WITH REMARKS.

BY WM. MACKENZIE,

Lecturer on the Eye in the University of Glasgow.

—

Living Cysticercus in the Anterior Chamber.

To the kindness and liberality of Mr. Meikle, of Edinburgh, the profession in Glasgow owe the opportunity of examining the child whose case has been published in a pamphlet by Mr. Logan, of New Lanark, under the title of "Animalcule in the Eye." The subject of this singular disease, a lively, healthy girl, of seven years of age, was presented at the Eye Infirmary on the 3d current, and the accuracy of Mr.

Logan's account fully recognized by a great number of observers.

It would appear, that, from the month of August till about the middle of January last, when she was first brought to Mr. Logan, this child had suffered repeated attacks of inflammation in the left eye. Mr. L. found the cornea so nebulous, and the ophthalmia so severe, that he dreaded a total loss of sight. He treated the case as one of strumous ophthalmia; and after the use of alterative remedies, and the application of a blister behind the ear, the inflammatory symptoms subsided, leaving, however, a slight opacity of the lower part of the cornea. After a week, the child was again brought to Mr. L. who, on examining the eye, discovered, to his great surprise, a semitransparent body, of about two lines in diameter, floating unattached in the anterior chamber. This body appeared almost perfectly spherical, except that there proceeded from its lower edge a slender process, of a white colour, with a slightly bulbous extremity, not unlike the proboscis of the common house-fly. This

process Mr. L. observed to be of greater specific gravity than the spherical or cystic portion, so that it always turned into the most depending position. He also remarked that it was projected or elongated from time to time, and again retracted, so as to be completely hid within the cystic portion, while this, in its turn, also assumed various changes of form, explicable only on the supposition of the whole constituting a living hydatid.

On the 3d current, when I had an opportunity of examining the case, I found the cornea slightly nebulous, the eye free from inflammation and pain, and the appearances and movements of the animal exactly such as described by Mr. Logan.

When the patient kept her head at rest, as she sat before me, in a moderate light, the animal covered the two lower thirds of the pupil. Watching it carefully, its cystic portion was seen to become more or less spherical, and then to assume a flattened form, while its proboscis I saw at one moment thrust suddenly down to the bottom of the an-

FIG. 1.

FIG. 2.

terior chamber, and at the next drawn up so completely as scarcely to be visible. Mr. Meikle turned the child's head gently back, and instantly the hydatid revolved through the aqueous humour, so that the proboscis fell to the upper edge of the cornea, now become the more depending part. On the child again leaning forward, it settled like a little balloon in its former position, preventing the patient from seeing objects directly before her or below the level of the eye, but permitting the vision of such as were placed above.

Mr. Logan has observed no increase of size in the animal while it was under his inspection. Mr. Meikle had watched it carefully for three weeks, without observing any other change than a slight increase in the opacity of the cystic portion. Mr. L. inclines to think that it is not likely to attain a larger size, and trusts that its natural period of existence

coming to a close, will free the eye from the danger of disorganization.

To the sagacity of Mr. Logan, then, we are indebted for the detection of this second instance of a living cysticercus existing in the anterior chamber of the human eye. The first instance on record came under the observation of the younger Soemmerring, and is referred to in the following manner by Schmalz, in one of the notes attached to his excellent selection of entozoological plates.

"Quod si lector de situ insolito horum animalculorum obstupescit, alium, cumque multo magis mirum, domicilium entozoorum modum, gratissima epistola a viro venerabili Sam. Thom. de Soemmerring mihi communicatum, publici juris facio. Contigit nimirum viro exc. Dr. Guil. Soemmerring (filio), testibus multis medicis Francofurti ad Moenum habitantibus, cysticercum vivum in puellæ cujusdam camera oculi

antere libere natantem observare. Parasitus nullum aliud symptoma, nisi, quando supra pupillæ marginem assur-rexit, impedimentum visus, excitavit *."

The description applies *verbatim* to Mr. Logan's case.

The cysticercus is a parasitical genus, plentifully found in the lower animals. It attaches itself principally to the cellular and serous membranes. In swine, it often abounds also between the fibres of the muscles, and sometimes multiplies to such an excess as to penetrate into almost every organ, not excepting the heart, the brain, nor the eyes†. Hares and rabbits generally contain this kind of hydatid; which is also found in some fish.

Specific differences are found in the cysticerci of different animals, but they all agree in presenting a cystic portion, containing a little liquid, and at one end a small spot, whiter than the rest, which is the proboscis in a state of retraction.

In all the representations which have been published of the cysticercus, the proboscis is represented uppermost‡; but we now know, from Mr. Logan's case, that this is the heavier part of the animal, so that in a fluid the cyst swims with the proboscis directed downwards.

The question has naturally occurred to every one who has seen or heard of Mr. Logan's case, ought not this animal to be removed from the eye? Mr. Logan and Mr. Meikle appear to have deferred employing any means for destroying or removing it; first, because it seemed to be producing no mischief, and, secondly, because there was a probability that it was a short-lived animal, and likely, therefore, speedily to perish and sink away, so as to give no greater irritation than a shred of cuticular capsule. Mr. Logan mentions, that should the hydatid shew any signs of propagation, a question would then arise regarding the necessity of abstracting it by an operation. Various means, however, naturally suggest themselves for killing the animal in its present situation; after which, it might either be left in the eye or removed by a puncture of the cornea, according to circumstances. Slight electric or galvanic shocks, passed through the eye, would probably deprive

it of life; oil of turpentine might be rubbed round the orbital region, and given internally in small doses, as I understand was suggested by Mr. Rhind; or the child might be put on a course of sulphate of quina, or of some other vegetable bitter known to be inimical to the life of parasitical animals. Should such means fail, there could be no doubt of the propriety of opening the cornea and removing the hydatid; even should we thus be deprived of an opportunity of observing the propagation of the cysticercus—a process which is probably effected, as in the echinococcus or common hydatid, by buds arising on the internal surface of the cyst.

As the child who is the subject of this extraordinary case appears to be in perfect health, we are led to think that the other organs are perfectly free from hydatids, and that a change of diet would have no effect upon the solitary individual in the aqueous humour. Had the patient, on the contrary, presented a cachectic constitution, with pale complexion, tumid belly, debility, and fever, none of which symptoms are present, we should have been led to suspect that what was visible in the eye was but a sample of innumerable hydatids in the internal organs of the body, and might have proceeded to try the effects of a change of diet with some hopes of success. Bremser is of opinion that the cysticerci often perish from this cause, both in man and in the lower animals; and, in illustration, states the following fact. Desirous of obtaining a quantity of cysticerci, in order to study anew their economy, he ordered the butcher to send him such a sow as he could vouch, from its external appearance, to be filled with this kind of hydatid. This was done accordingly; but before killing the animal, Bremser kept it for a short time, in the hope of obtaining still more cysticerci. He probably fed it on substances different from those it had been accustomed to, for he failed completely in his object. On killing the sow, only some twelve or fifteen hydatids were obtained*.

PRACTICAL REMARKS
ON
DYSENTERY.

By T. SPENCE, 52d Regiment.

[Concluded from page 77.]

—
In the treatment this pathology must ever be kept in view; and if what I have said be true, it will prove the absurdity, the danger, of adopting any one of the methods which have been recommended, to the exclusion of the others; for instance, when the intestines are ulcerated, calomel even in scruple doses, increases much the mischief, producing more repeated purging, and often copious discharges of blood, keeping up constant irritation and considerable griping. Again, it were vain to suppose, when the disease has advanced so far, that ipecacuan. or any other sudorific, can heal the ulcers. Purgatives of a drastic nature make matters ten times worse. Bleeding too, when the ulcerative process has begun, will only have the effect of increasing the debility of the already nearly exhausted individual;—whereas, each of these measures, if adopted under proper circumstances, and at a fit time, will have a good effect. The mercury, when the liver is affected, and before the inflammation of the intestines has passed into ulceration, will have a wonderful influence, and of all others is perhaps the best remedy; it changes the quality of the bile, removes obstructions, &c. &c., and thus taking away the exciting cause, stops the progress of the disease. Again, when dysentery arises from irritating matters, be they what they may, whether indigestible substances, scybala, or vitiated bile, a purgative, for instance castor oil or enemata, must be beneficial in dislodging the cause of irritation. Further, in cases which are attended with high febrile action at the commencement of the attack, general bleeding will be very serviceable; here, indeed, a combination of means will be necessary, viz. bleeding, sudorifics, and mercury, with mild purgatives, each being indicated.

On a soldier presenting himself to me with a bowel complaint, I invariably order him to be put into a hot bath, and administer half an ounce of castor oil, with ten or fifteen drops of tincture of opium; after which, from the appear-

ance of the evacuations, I am the better able to judge of the nature of the affection. Should they be brown and liquid, or of a bilious character, or of a light colour, it is most probable that the liver is implicated, which the state of the tongue and uneasiness in the side will generally corroborate; and then, if the case be recent, I determine to pursue the mercurial plan, and howsoever adjuvants may be employed, this is the main stay.

I have not the least fear to bleed in this disease, and am regulated by the state of the pulse, skin, and constitution of the patient, but in the majority of such cases I prefer the free use of leeches, three or four dozen, or more, to the side or lower part of the abdomen, according to the seat of pain; the bleeding to be encouraged by the application of hot flannels. The leeches will require to be frequently repeated upon any return of the pain or straining. The calomel may be given in scruple doses three times a day; or if so large a dose be objected to, from three to six grains every three hours, with ten grains of Dover's powder, will answer the purpose well, and generally affect the system in thirty-six or forty-eight hours. Opium, in masses of four, six, or eight grains, may be introduced into the rectum, and in this way will be found more beneficial than when taken by the mouth; it diminishes very much the tenesmus, and by allaying the pain procures considerable tranquillity to the patient. If by these means the pyalism be reduced, the pain relieved, and the evacuations less frequent, and of more natural appearance, the prognosis may be favourable, and nothing but a little castor oil, a regulated diet, and attention to warmth, will be necessary to complete the cure. But there are many cases in which the mercury has not this good effect; and even if persevered in to an enormous extent, only ulcerates the gums; so that if I find in the time I have mentioned, when about 120 grains of calomel have been given, that there are no signs of pyalism, I take nature's hint, and go upon the other tack, for, under such circumstances, to continue the administration of this medicine I believe to be very injurious. If the calomel increase the purging, or pain in the abdomen, it must not be persevered in from the first, but other symptoms indicating the necessity,

mercurial frictions are to be adopted instead, which, though less efficacious, is all that can be done; then leeches from time to time applied to the hypogastrium, frequent fomentations, with large and often repeated doses of Dover's powder, will tend at least to diminish the sufferings of the patient. When the mercury disagrees with him in the way I have mentioned, it is almost a certain indication of the mucous membrane being ulcerated, and then in the evacuations there will be more or less of the flaky and curdy matter to which I have alluded; and the discharges of blood are often very copious, the pain in the abdomen will be more constant and severe, the pulse quicker, and the countenance sunk, with a depression under the lower eye-lid; the expression becomes anxious and ghastly. In these cases, I fear the physician must play the part of second only, for his efforts to cure the disease will all be ineffectual; nature must be the chief operator. We, however, may assist materially; and with this view I would recommend a nutritious simple diet, in the shape of jellies, beef-tea, panada, or raw eggs beat up with a little sugar. Nothing should be administered which can by any chance irritate the intestines, but at the same time the system must be supported by sufficient nourishment. Sudorifics, such as Dover's powder, will be serviceable, with fomentations to the abdomen: emollient enemata, consisting of decoction of poppies, or barley-water and oil, with laudanum, are exceedingly useful. Great caution and gentleness is necessary in the administration of these injections, as, if this be not attended to, incalculable mischief may be done. After the enema, an opium suppository should be introduced, and on any exacerbation of pain not allayed by the fomentations, a dozen or two of leeches must be applied.

With regard to stimulants in the ulcerated stage of dysentery, I have but a few words to say; they may be beneficial, and they may be very prejudicial; and therefore, in their application, the utmost care and discrimination are required. I have seen the administration of the sulphate of quinine and port wine assist materially in the recovery of several patients; and I had the misfortune to witness the death of a most excellent man hastened, if not caused, by the ignorance and obstinacy of his medical

attendant, who, in spite of remonstrance, persisted in giving his patient a bottle of Madeira, or more, in the day. I was present at the examination of the body; there were two or three small abscesses in the liver, and the cæcum was the most perfect specimen of disorganization I ever saw. If, then, stimuli have neither the effect of increasing the griping, straining, or purging, augmenting the force or frequency of the pulse, or heating the skin, they may be continued, but only under those circumstances.

If a case of dysentery occur from checked perspiration, or cold taken in any way, and the disease be attended with high febrile excitement, the pulse being quick and the skin heated, with severe tenesmus, tormina, and tenderness of the abdomen, the stools consisting of little but mucus and blood, and the individual having been previously healthy, then we must not be sparing in the abstraction of blood generally. I have repeatedly taken from lbj. to lbiss. with decided benefit. The patient should be put into the hot bath, and from three to five grains of ipecacuanha administered every three or four hours, or as much and as often repeated as will keep up slight nausea: to make him drink at the same time largely of hot water or tea, will have an excellent effect, as by this means copious perspiration will soon be excited, the fever will subside, and the inflammation of the intestines be reduced, for here there has been no time for ulceration to take place. After this, a few grains of calomel, and a little castor oil, with abstinence for a few days, will be all that is required. This is taking a favourable view of the case, and there are indeed many which do not terminate so happily; however there will, I am certain, be a sufficient number to justify this method. The application of leeches to the abdomen in all cases, as an adjuvant, is of infinite service; there is scarcely a stage of the complaint in which they may not be employed. Blisters I have been induced occasionally to apply, but have not much confidence in their benefit; moreover, they prevent the application of leeches and fomentations, which are far more useful agents. With regard to purgatives, excepting castor oil, I can scarcely condemn them in sufficiently strong language, and I am convinced that I have seen the death of several men

occasioned by their indiscriminate use; indeed, I can scarcely conceive a more dangerous practice than the daily administration of the sulphate of magnesia in dysenteric cases.

In the form which has been denominated scorbutic dysentery, there is great nicety required. Bleeding is out of the question, as the patient is generally in a debilitated and relaxed state; and I fancy few people would be disposed, under such circumstances, to venture upon mercury. I have generally adopted the sudorific plan, consisting of Dover's powder, with fomentations and warm baths, and most minute doses of castor oil now and then. Lime juice, with brandy, hot water, and laudanum, are under these circumstances a very efficacious combination, producing sleep, and great relief from the griping and purging. This form is seldom very acute, but consists in a chronic ulceration of the intestines. In those cases which I have examined after death, there has seldom been any evidence of inflammation beyond the ulcers, which were small, circular, and with unelevated edges. Warm clothing is here a very important means; the whole surface should be covered with flannel; the diet should be nutritious, but mild and easily digested; and a glass or two of port wine may be taken daily with great advantage. But a change of air to a climate where the atmosphere is dry and clear is indispensable, as without this all other measures will be ineffectual.

NATURE OF THE VENOUS OPENINGS IN THE SIDES OF THE UTERUS—PRIORITY OF THEIR DISCOVERY.

To the Editor of the Medical Gazette.

SIR,
THE leading article of your journal of the 13th instant contains a faithful exposition of what is known upon those interesting and intricate subjects—the structure of the placenta, and “the communication between the mother and the fetus.” In conceding, however, to Dr. Robert Lee the palm of originality for the alleged discovery that the openings which he, in common with many others, has described upon the surface of the uterus, are natural apertures in

the sides of the veins, you appear to have granted more than was ever claimed by him. The existence, indeed, of such orifices you have clearly shewn to have been, and to continue, “the doctrine of the highest authorities upon this point;” but that these are *apertures in the sides of the veins*, I cannot find that either Mr. Owen, or Dr. R. Lee, has with distinctness, if at all, asserted. Mr. Owen, if he has formed any definite notion upon the subject, inclines to the opinion that they are the *extremities* of veins, not holes in their course; for he says, “In every instance the vein, having reached the inner surface of the uterus, *terminated in an open mouth* on that aspect;” and again, “but with respect to the veins, they invariably presented the same appearances as were noticed in the first dissection, *terminating* in open semicircular orifices, which are closed by the apposition of the deciduous membrane and placenta.” Dr. R. Lee is even less explicit, describing these oval apertures merely as “openings leading obliquely through the inner membrane of the uterus, and large enough to admit the point of the little finger,” with smooth edges, having no appearance of laceration, and covered and closed by the deciduous membrane; and again, in a recent number of a contemporary journal, although he avers that no writer in this country, or on the continent, so far as he knows, has described them as natural apertures, he contents himself with calling them “*great openings in the lining membrane* of the uterus, which are closed by the decidua during pregnancy, and by which, after the removal of the placenta, a free communication is established between the cavity of the organ, and the uterine sinuses containing the maternal blood.” Dr. R. Lee, then, has advanced nothing upon the subject of the precise nature of these orifices; and as he has left it uncertain whether he considers them as the commencement or termination of veins, as holes in their sides, or as new and accessory tubular communications between the surface of the uterus and its sinuses, it cannot be a source of dissatisfaction or annoyance to him, if it be successfully shewn that the existence of such openings *in the sides* of the veins had been distinctly announced just fifty years ago, in a well-known and ponderous volume upon midwifery, by Dr.

Robert Wallace Johnson, who distinctly describes these apertures *in the sides* of the veins as existing in the unimpregnated uterus—as having a free communication with the whole venous system of that organ—as being the source of the catamenia—as becoming enlarged during pregnancy—as assisting to nourish the ovum in the early months—and as receiving fluids from the placenta in the more advanced periods of gestation.

As, however, the work of Dr. Johnson may not be in the hands, or within the reach, of many of your readers, it may not be uninteresting to detail the observations and experiments by which he has endeavoured to establish each of the foregoing propositions; and 1st, in proof that these lateral orifices really exist in the unimpregnated uterus, he says (p. 21), “the inner surface of the body of the uterus is covered with a very fine fibrous shag or villi, amongst which there are many small apertures (as have appeared to me), or oblong orifices, which open from the sides of those veins that lie next to this surface.”

2dly, To prove that these apertures, upon the surface, have a free communication with the veins of the uterus, he adduces an experiment (the less obnoxious to objection as it was intended for another object), instituted at his suggestion, and in his presence, “by that experienced and most excellent anatomist and surgeon, Mr. John Hunter.” He says (pp. 28, 29), “We first tied the extremities of those (fallopian) tubes near to the fimbriae; then, having filled a syringe with flake-white and water, we placed it in the vagina, so as to make its pipe correspond with the *os tincæ*, and bound it fast. This being done, the injection was then forced into the cavity of the uterus: the result of which was, that by the time the cavity of the uterus was well filled, the injection ran out at the sections of the spermatic and hypogastric veins, which sections were in the duplicature of the broad ligaments, at the distance of above an inch from the sides of the uterus, and which we left untied.” . . . “By inspecting the inner surface of the uterus, we observed there were many small apertures, or orifices, through which the injection had passed from the cavity into the uterine veins; and, by dividing the uterus into several pieces, we found that the injection (*viz.* the white part of it) did remain in the veins through most of them.”

3dly, He thus (p. 31.) supports his opinion, that from these orifices the menstrual evacuation proceeds:—“What I have advanced concerning the apertures, called *lateral orifices*, may perhaps occasion some matter for dispute, especially among those who are very fond of controversies; because, as far as I know, these orifices, which have been observed on the inner surface of the uterus, have not been explained in the same way. . . . As soon as I had wrote the two cases above-mentioned, I shewed them to several of my friends, informing them, at the same time, that it was my real opinion, the menstrual flux must be made by those orifices, and not from the extremities of arteries, as commonly believed. Nevertheless, about four years afterwards, being desirous to know more particularly what had been said on the subject, I looked into the works of such authors as I could meet with, and found several—namely, 1mo. Highmore; 2do. Spigelius; 3tio. Mauriceau; 4to. Winslow; 5to. Littre; 6to. Morgagni; and, 7mo. Dr. Burton—had mentioned, their having seen orifices on the inner surface of the uterus filled with blood, especially in women who had been banded, or in those who had died in the time of the catamenia; which orifices I believe to have been such as I have described.”

4thly, Having described with fidelity and accuracy, scarcely exceeded even by Mr. Owen, in his communication to Dr. R. Lee, the large anastomosing veins of the uterus, with communicating apertures, in some instances “so large, as to receive the end of a goose’s quill,” and which he observed in a woman who had died undelivered in advanced gestation, he proceeds to describe the lateral orifices thus, (p. 30): “The inner coat of the body, namely, that surface which surrounds the cavity of the uterus, was covered with a villi, or shag, somewhat deeper than in the virgin state; amongst which the apertures, which I here call the *lateral orifices*, of the uterine veins were manifest, and appeared as if made by the point of a lancet in the direction of the veins.”

5thly, Dr. Johnson was of opinion, that these apertures contributed, in the early months of pregnancy, to the nourishment of the ovum. So he says, (p. 62.) “Now as the fœtus acquires form and bulk, a greater quantity of nutritive fluids will be required from the mother. During this early stage it is not improbable that the walls of the

ovum should absorb those fluids from the orifices described in chap. v. § 8., seeing no arteries, that I know of, have been observed to terminate upon the inner surface of the uterus before pregnancy."

But, 6thly, in advanced gestation, Dr. Johnson believed, that instead of these orifices affording nourishment to the ovum, they became the recipients of fluids from the placenta; adding, (at p. 63) "but after this time the ovum enlarges, the placenta adheres firmer, and grows considerably thicker, so that its spongy texture is very probably soon adapted to receive into its cells the fluids from the extremities of arterial branches without losing its adhesion; and now the lateral orifices of the veins become fit to receive those fluids from the placenta which are to pass from the fœtus to the mother."

Such, then, is the first and only account that I have met with of lateral apertures in the veins upon the surface of the uterus. Dr. Johnson believed in their existence, at all events, as early as November 1757, when Mr. John Hunter injected them in his presence; and his observations are not only interesting in themselves, but are more especially so with reference to the question which has been recently agitated with more of the keenness and acrimony of personal controversy, than of the calmness and dignity of philosophical inquiry. It is not very material whether I coincide with these views of Dr. R. W. Johnson or not; it is not my object either to uphold or controvert them. I had no other intention than to remind you of a work which seemed to have escaped your observation; and to satisfy you that there is no novelty in the opinion, that, in the course of the veins, there exist lateral orifices, which are now supposed to have a most important connexion, not only with the ordinary functions of the uterus, but with some of the more serious pathological conditions of that organ.

Your constant reader,

H. HUGHSON.

London, April 17, 1833.

TAX ON ANATOMY.

To the Editor of the Medical Gazette.

SIR,

I READ with no little astonishment in the Medical Gazette of this day's date,

that it is the intention of the Home Secretary to defray the police charges incidental to the operation of "the Anatomy Bill," by a tax levied on individual members of the medical profession. Should Government really have any such intention, they would be guilty of gross injustice, and, as I conceive, of a direct breach of faith in the measure proposed. I beg, sir, to recal your attention, and that of your readers, to a correspondence which took place on this subject when the Act first came into operation, and which is published in your journal of September 15, 1832. In a letter, dated September 11, 1832, and signed by G. Lamb, you will find it stated that Lord Melbourne "has given directions (with a view of reducing the expense to the parties as far as the official regulations will admit of), that any number of persons requiring a license to practise anatomy at the same place, shall be included in the same license; and that, in those cases where it may be necessary to renew any license, on account of a change of residence, no fee whatever will be charged for such renewed license."

This letter, signed by the Under Secretary, was written in reply to one resisting the demand of an "office fee" of 2*l.* 2*s.* 6*d.* on the issue of the anatomical license. In it no hint is given of any "understanding" between Government and the framers of the Bill, that the arrangements for meeting its expenses, and which are specified in clause 6 of the Act, should not "be considered as permanent." Under the provision of this clause, the inspector's salary and other necessary expenses are charged upon the Consolidated Fund; and it is further ordered, that a return of all such disbursements shall be annually made to Parliament. There is no mention in the Act of "office or other fee," or of tax of any description, to be levied on the medical profession, for the purpose of ensuring the benefits of anatomical science to the public at large. By the correspondence to which I have referred, it will be seen that no such unjust intention was entertained by the Government when the Act first came into operation. I do sincerely hope, sir, that the profession will find sufficient spirit to resist the imposition of this partial and insulting tax. By submitting to it, we should compromise a great principle—that, I mean, by which the im-

portance of anatomy as a PUBLIC BENEFIT to all ranks of men is asserted. The Act of Parliament under which it is now proposed to raise a new tax from us of the medical profession, was framed and passed, not for our exclusive advantage, but for the prevention of murder, and for the protection of Anatomical science, in the interest of the entire Public.

It was not *our* fault, it was not *our* shame, that, until within the last six months, Anatomy in England implied Murder, and that, by the English laws, the Anatomist was degraded to the level of the public Executioner. By *paying* for the Act, by *purchasing* it as a *bargain* from the Home Office, we should appear to recognize in its provisions a source of special professional advantage to ourselves, which, in our own credit, and for the tranquillity of the public mind in this matter, we should surely be slow to admit. The Inspector of Anatomical Schools should be well paid (much better paid than he is by the Act as it now stands); but most certainly he should not be paid by the Teachers and Students in Anatomy. The Bill, be it remembered, sir, is *not* a source of profit to teachers and students; great trouble and great expense are still imposed on them by its enactments. The cost of a single opportunity for dissection is still nearly twelve times what it would be in the schools of Paris. One of the reasons advanced for the enactment of the statute was, that Anatomy was rendered impossible to many, by the expense incurred in the pursuit of it. We are *now* told, that its opportunities have become too cheap and too easy, and *therefore* that the student should be further taxed for the advantages which he enjoys under the Bill. The Act, sir, was never intended—was not granted—as “a boon to the profession.” Its objects are stated in the preamble; they are, the promotion of a public benefit—the prevention of public crime. It would be idle to threaten the profession with the repeal of the Act, should they not consent to *buy* it from the Minister. Anatomy *cannot* be repealed in England at this time; it will never again be suffered by the English Public to depend on Sacrilege and on Murder for its support. The Minister would not DARE to withdraw the Act from operation. It would be the direct personal interest of every man afflicted with Hernia, or with Fistula, (and there are many of all parties,

in office and out of office, in this predicament)—it would be the interest of every one liable to Aneurism, or to fracture of his limbs, (and who is not liable to such heritage of ills in the flesh?)—it would be the interest of one and all to insist on full and proper protection being afforded to the study of Anatomy in England. Parliament surely will not grudge the trifling sum in which it is PLEDGED by the Act, for the security of the Public Health, as influenced by the cultivation, or (I would rather say) the very existence of Anatomy as a study, in this country? I am at a loss to conceive on what possible pretext the minister can apply to the profession for pecuniary help in this matter. It is a painful, indeed frightful evidence, of the state of our public finance, that an attempt is thus made to extort from individuals the payment of a sum so small in itself, and guaranteed by parliament from the public funds for a public purpose. We are told, that the “Anatomical Teachers” have given it as their opinion, that the tax should be levied on the profession by a stamp duty; that the physicians and surgeons of England *ought* to pay the police charges, for the prevention of Murder, and for the protection of Anatomical Science from legal or popular outrage. I deeply regret that the Anatomical Teachers should have given any such opinion. I am truly surprised that any member of the present liberal government should have thought fit to urge them to the declaration of such opinion. Many of them, must, I should think, now regret having thus committed themselves; and the more so, as the “opinion” is not in any way binding on the general body of the Profession, whose interests are so much involved in the matter to which it relates. The objections that could be made to this tax on the Profession, are many more than I have stated in the weak, hurried letter, which I have addressed to you. It will be for others to prove that such tax is illegal and unconstitutional. My object has been to direct the attention of the Profession to its injustice, and to the slight which is thereby put upon Anatomy; thus seemingly recognized by the government as the affair and interest of a particular “set of men,” rather than of the public at large. The bill, let it be repeated, was not passed for the advantage of a trading profession of medical practi-

tioners, but for the security, the comfort, and well-being, of the people of all England. I should not have written to you, sir, on this subject, had I not felt that the character and consequence of the Profession were in some measure compromised by it. I moreover, in consistency, think it my duty to persevere in the opposition which I made, in the autumn of last year, to the exaction of fees, under the new Act, which are not warranted by its provisions. Should the Profession think right to submit to the tax, which, as you inform us, it is now proposed to levy on them, I venture to express a hope that they will at least insist on knowing its exact amount, the purposes to which it is applied, and the manner of its distribution.

I am, sir,
Your obedient servant,
A PHYSICIAN.

London, April 20, 1833.

MEDICAL GAZETTE.

Saturday, April 27, 1833.

“Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

INFLUENCE OF EPIDEMICS.

ANXIOUS as we ever are to vindicate the merits, and to shew, when it is practicable, the superiority of many of our own national arrangements, we yet meet occasionally with instances in which we must confess the practice of neighbouring states seems to be decidedly preferable. Not to go farther than France, we think that among the points connected with medical matters, in which that country deserves the praise of managing better than we do, are the attention which it gives, and the encouragement which it holds out, to statistical inquirers. The consequence is, that men of the highest talent and attainments engage themselves in that capacity, and that results arise as extensively beneficial as they are eminently creditable to the nation in which they

originate. The value of statistical researches is not confined to the country in which they are conducted; the general conclusions, at least, are more or less adapted to all places bearing any resemblance in their circumstances; and when our own inquiries of this nature fall short, as in many respects most lamentably they do, we may beneficially avail ourselves of the exact data which we shall find in any other European state. Thus, on the subject of epidemics—a subject of great and growing importance—we may profitably make ourselves acquainted with some late researches by distinguished foreign writers, and particularly those by Professor Alibert, and M. Villermé, in France. The former of these authors has published an elaborate paper on the secret causes of epidemics*, in which he examines the relation which maladies of this class bear to variations of temperature, and to the emanations which are derived from the three kingdoms of nature: but though there is much that is valuable in the opinions set forth in his paper, as well as not a few points that might be profitably discussed, and not unreasonably controverted, we cannot properly give any account of it at present, as the entire of M. Alibert's views have not yet been laid before the public. In the meantime we have the masterly essay on epidemics by M. Villermé before us†, and of this we purpose, on the present occasion, to give a slight sketch.

The author opens with some remarks on the influence which civilization has had on the frequency and intensity of epidemics. Without going back to dark or distant periods, when statistics were little or not at all attended to, his principal facts are derived from the authenticated histories of the last century;

* *Revue Médicale*, Janv. 1833.

† *Annales d'Hygiène Publique et de Médecine Légale*; Janv. 1833.

and he it observed that he makes a special exception, among the epidemics of which he treats, with regard to such scourges as the black plague of the fourteenth century, and the blue plague, or the cholera of our own times. These, he says, have been calamities that bid defiance to our reasonings, extraordinary, occurring at distant intervals, and inscrutable as to their causes. Those occurrences, on the contrary, of which he treats, seem chiefly to depend on temperature and its sudden alternations, on certain qualities of the air, on the diet, the habits, or local peculiarities of the people among whom they are observed.

Since the frightful epidemic of northern Europe, and particularly of Dantzic, in the years 1709 and 1710, chiefly attributable to scarcity and famine, happily nothing of the kind has been experienced in modern times. Agriculture, it is well known, has since been more successfully cultivated—its principles are better understood, and especially the mode of managing the crops so that they may succeed each other in rich variety; the communication between distant parts has been rendered more easy; people lodge better, live better, and are better clad than at former periods; and by means of improved manufactures and the multiplied resources of industry, together with better modes of government, the population in all European countries has been greatly benefitted—comfort is more widely diffused, and the occurrence of starvation and its consequences have become every where less to be apprehended.

Take Viareggio as an example. The inhabitants of this once miserable town in the principality of Lucca, were few in number, and sunk in a deplorable state of misery and barbarism—year after year, from time immemorial, they were regularly attacked with intermittents

In the year 1741, however, sluices were constructed, by which the marshes in their neighbourhood were drained, and at the same time the overflowing of the land from the tides and tempests prevented. By this simple contrivance their constant epidemic was banished, and Viareggio soon became what it is at this day—one of the most healthy, most industrious, and affluent seaport towns on the coast of Tuscany; and families in it, whose immediate ancestors used to be cut off prematurely and miserably by the *aria cattiva*, now exhibit a degree of health, vigour, longevity, and moral character, such as was never known in that part of the world before.

Dr. Thomas Short, who wrote his "Observations" about the middle of the last century, makes a remark strongly attesting the power of civilization—namely, that epidemics in the country parts are both more frequent and more destructive than they are in towns. In London, and the other principal cities of the kingdom, according to this author, the epidemics which occurred in the early part of the last century generally carried off no more than a third, a fourth, or even a fifth part, in addition to the usual mortality of common years; whilst, in the country, an epidemic year sometimes numbered with the dead ten, fifteen, eighteen, or twenty times as many as died during a healthy year. M. Villermé has made the same observation with reference to the mortality in France.

Now with regard to the comparative frequency of epidemics at different periods during the last and present centuries, we may avail ourselves of the same authority for information. Dr. Short calculates, that, previous to 1750, they recurred every four, or from that to eight years, in the country parishes of England; a fact which he gathered from the parish registers: and the conclusion at which he arrives is, that the

years decidedly epidemic, as compared to other years, were in the ratio of two to eleven; and that of forty-four consecutive years, from twenty-three to twenty-four counted a small number of deaths, eight were very destructive, and the remaining twelve or thirteen could neither be called salubrious or otherwise. We have no exact returns of the same description for London or the provincial towns, but we may form a pretty adequate notion of at least the decline in the frequency of epidemics visiting them, from M. Villermé's table for Paris. In drawing up the following tabular form, which is here slightly abridged, the author reckoned as epidemic years those in which there was an increase of deaths amounting to more than one-tenth above those immediately before or after. He found that there were

6 epidemic years out of 13, in the 17th century.	
5	from 1709 to 1720 inclusive.
5	1731 to 1740 . .
4	1741 to 1750 . .
4	1761 to 1770 . .
4	1781 to 1790 . .
3	1801 to 1810 . .
2	1821 to 1830 . .

A similar return shews that a change equally prosperous has occurred throughout the whole of France, and M. Villermé justly assumes that we cannot have a stronger proof of the happy influence of advancing civilization.

There are some facts connected with the decline of epidemics in Paris, which are too curious to be omitted here. Formerly, the end of summer, especially when that season had been unusually warm, was the time for epidemic maladies. Thus the months of August and September (the latter particularly), were, during the latter part of the 17th, and beginning of the 18th century, notoriously fatal. But this appears to be quite changed at present. By a comprehensive table, founded on two millions of deaths, and extending from the

end of the 17th century to our own times, M. Villermé shews that the periods of the *maximum* and *minimum* mortality are altogether displaced. Disposing the twelve months in the order of their respective mortality, September, which stood first at the early period referred to, has gradually sunk to the place which it now occupies, the seventh or eighth in the series; while April, which in former times seems to have been comparatively salubrious, has long been raised to the head of the list. The alteration is clearly owing to the decline of epidemics, both in frequency and intensity: when they used to rage, as in the 17th century, the maximum mortality fell in the autumn, while now, under the influence of ordinary circumstances, it occurs in the spring.

The effect of epidemics on other diseases does not escape the notice of M. Villermé. What he says on this subject we shall lay before the reader:—"It is the nature of epidemic maladies to render other complaints more rare. This has been observed often enough by physicians; they are familiar with the fact, that while an epidemic reigns, other maladies diminish in frequency, or exhibit more or less of the symptoms of the prevailing disease. In the month of April last, when the cholera prevailed here, we had a good example of this. But the practical consequence to be derived from the circumstance is, that when an epidemic is not particularly destructive, the usual number of deaths is not much, or scarcely at all, augmented. One might imagine that those persons who at ordinary periods would die of various deaths, now die of the prevailing one, as if the special causes of the latter, its very existence, or the circumstances which attend it, were so many preventatives of the ordinary mortal diseases. Thus in the 47 communes of the department of the Oise, which reckoned, in 1821, 116

deaths from the *miliary-sweat*, the total mortality did not exceed what it reasonably ought to be, taking into consideration the rate of increase of population, and supposing that no extraordinary cause of mortality existed during that year. For example, in the said communities,

In 1816 there were 709 deaths.				
1817	.	.	.	735 . .
1818	.	.	.	718 . .
1819	.	.	.	787 . .
1820	.	.	.	813 . .
1821 (Epid.)	.	.	.	838 . .

The result to be deduced from this and similar facts is, that epidemics, generally speaking, do not warrant the alarm which their appearance ordinarily excites. It is, however, unquestionable that they always increase the number of the sick, as well as that they have often depopulated whole countries."

To an inexperienced observer it would seem almost idle and ridiculous to inquire whether epidemics affect the population of a country, and paradoxical to assert, that even those which are considerably destructive do not. Yet such is the case which correct statistics would seem to make out; and it is accounted for on no very abstruse principle. It is simply because epidemics, for the most part, partake the character described in the preceding passage by M. Villermé, namely, that of swallowing up the mortality of ordinary diseases; and partly, if not principally, because mortality has a powerful influence upon reproduction. An epidemic may be compared to a battle in its effects; yet a battle—nay, a war of ten, fifteen, or twenty years' standing—may not diminish the population of the states which carry it on. That it may not, seems to be put beyond a question by the sanguinary war which raged in Europe from 1791 till 1815; during all that time the number of inhabitants in France, England, Germany, and Italy, suffered no decrease, and that in spite of the constant battles, in

which too the mortality fell upon men in the full strength and vigour of their age.

But when we say that there was no decrease, we ought to qualify the expression: any decrease which occurred was not permanent: the movement of the population, after suffering a slight shock, went forward again with a renewed impulse; and so it is with epidemics.

When a destructive calamity of either kind carries off a large proportion of the inhabitants of a country, a void in the population is the immediate effect; but invariably this is followed by an extraordinary proportion of marriages and births. Numbers of persons of a marriageable age, having most probably now become possessed of the means by inheritance, hesitate no longer to form matrimonial connexions. Marriages even which were barren hitherto, are now observed to become fruitful. And finally, the returns shew that not only is the annual amount of deaths diminished, but its proportion also,—as if men had really become more vivacious, or less subject to die.

Owing undoubtedly to the occurrence of such circumstances, it has become a common observation, that great epidemics are followed by periods of great salubrity. But the fact ought not to be overlooked, that on such occasions it is the ill-conditioned, sickly people, that for the most part are cut off—people wasted by suffering, and reduced by privations; while the survivors have more room, more food, and ampler means of subsistence.

The statistics of the Low Countries (Belgium and Holland united) confirm most fully the preceding statements. In the year 1815 there was, of course, a considerable increase in the number of deaths, but the increase in the number of marriages during the same year (chiefly contracted by military men,

who, on the return of peace, wished to secure themselves from the chance of being again called out,) was enormously large. Then followed a great increase of births in the next year. In 1817 there was a severe scarcity of provisions; the deaths were greatly augmented again; but when once order was restored, both marriages and births went on increasing prodigiously.

In extreme cases, however, we must allow that the consequences will be very different. It is the opinion of some writers that, in the course of eight or ten years, there are no longer any traces of ruin remaining in a country which has been devastated by the plague. This is a mere opinion, and must be altogether gratuitous, as it leaves out of sight the degree of intensity of the disorder, and the extent of country ravaged by it,—both which considerations are necessary to enable us to determine how long it will be before the population shall attain its natural level. It is more than probable, that there were abundant traces of devastation discernible ten years after the epidemic of 1709 and 1710, and still more so after the black plague of the 14th century. There must at least have been an over-proportion of young children compared with the other ages; just as, after a long and sanguinary war, the women, and, of the male sex, those who are not of an age to take a part in military service, are by far the most numerous.

Such are a few of the more striking topics treated of in this able paper; and seldom have topics so apparently unpromising been discussed in so satisfactory a manner. The author is clearly one of those rare investigators who see the better side of things, and take more delight in it than in the gloomy. The temper and tendency of his essay is encouraging, and practically useful. It shews in the strongest light the salutary consequences resulting to

the physical condition of man, from the spread of civilization. This is a fact which good governments might easily improve, and one which ought ever to be kept in view by all whose duty it is to labour for the benefit of mankind.

CHOLERA IN PORTUGAL.

THE London Merchant steamer sailed from England, for Oporto, on the 25th December, 1832, and arrived at the mouth of the Douro on the 1st January, 1833, having lost seven persons on her passage, by cholera. The troops which she took out, with General Solignac, landed immediately at Foz, about two miles to the west of Oporto. By a letter from a medical gentleman of that city, which we have lately seen, it appears that cases of the disease occurred at Foz, on the road to, and in Oporto, before the 15th of January; and we know, from other authentic sources, that it has since spread to Coimbra, on the south, and Galicia, (Vigo) on the north.

Quere—How did the cholera get to Oporto?

STATISTICS OF SUICIDE IN FRANCE.

M. GUERRY, the advocate, has presented a report on this subject to the *Academie des Sciences*, from which it appears, that, of the whole number of suicides committed in France, the department of the Seine supplies a sixth part, and that the proportion increases the nearer to Paris and the other large towns. Of 1000 suicides committed in the capital, 505 have been by persons belonging to the departments of the north, 210 of the east, 168 the south, 65 west, and 52 have been by persons from the central departments. The northern departments produce one suicide out of 9,853 inhabitants; the eastern, one out of 21,731; the central, one out of 27,393; the western, one out of 30,499; and the southern, one out of 30,876. Finally, of 100 suicides committed annually, 51 are by people in the north, 11 by those in the south, 16 in the east, 13 in the west, and 9 by the people in the central parts. —*Gazette des Hôpitaux*.

THE INFLUENZA.

THE number of new cases of influenza has been less during the last than the two preceding weeks; perhaps, however, this is to be attributed rather to the diminished number of persons who remain to be attacked, than to any change in the disease itself. On all former occasions which have been recorded, the epidemic has lasted from a month to six weeks, so that the time for its disappearance has perhaps scarcely yet arrived; and we fear a still more considerable period will elapse before all its sequelæ are got rid of. The complaint has proved very severe to many old persons; and those affected with any disease of the lungs have had the symptoms very much aggravated; while a very large proportion of those previously in the hospitals with other maladies, have had this superadded. Many attempt to explain these occurrences by a reference to the state of the weather, which certainly has hitherto been more than usually ungenial even for the proverbially fickle month of April; at the same time, the vicissitudes of the atmosphere will not account for the excessive languor, and many other circumstances, attending the prevalent form of illness; while the histories of former visitations of this kind, shew them to have been uninfluenced by any appreciable condition of the barometer, the thermometer, or the hygrometer.

JACKSONIAN PRIZE.

THE Jacksonian prize for 1832, offered for the best essay "on the Mode of Union in Simple and Compound Fracture," was awarded, by the Council of the College of Surgeons, to Benjamin Phillips, Esq. of Wimpole-Street, Cavendish-Square.

THE ANODYNE METALLIC OR GALVANIC BRUSH,

(*Scopula Anodyna Metallica. Annales Scholæ Clinicæ Medicæ Ticinensis. Auctore FRANCISCO NOB. AB. HILDENBRAND, M.D. Papiæ, 1830.*)

UNDER this name, Francis Ernest Von Hildenbrand, Professor of Pathology and Practice of Physic at Pavia, describes a remedy rather singular, for the cure of various neuralgic affections. It consists sim-

ply of a bundle of metallic wires (*fascis ejus metallicis confectum*), not thicker than common knitting wires, firmly tied together by wire of the same material, so as to form a cylinder about four or five inches long, and one inch or three-fourths of an inch in diameter. This is applied to the pained part, previously moistened with sea-salt, when it produces relief so instantaneous, it is said, that it appears to the patients like the effect of a charm. Occasionally the pain is immediately entirely extinguished, with the accompanying effect of a peculiar sense of emanation from the spot to which the brush is applied, causing the patients to believe that the pain is truly extracted by this method. On withdrawing the brush, the uneasiness occasionally returns, but in a more endurable form. The longer the application is continued, the more decided is the effect obtained; and phenomena so singular have resulted from its application, as even to astonish intelligent persons quite on their guard against any magical illusion.

In illustration of the remedial effects of this agent, Hildenbrand mentions the following case, which he designates as altogether singular and wonderful. A man of 30, a porter by occupation, afflicted with violent periodical tic douloureux of the face (*metopodunia*), was admitted into the clinical wards of Pavia. On applying the metallic brush over the left frontal nerve, the pain immediately disappeared from that one, but fixed on the corresponding nerve of the right side, which had been previously free from pain. The very moment at which the brush was removed from the left frontal nerve, the pain returned to its original seat, and there remained, though already remarkably abated in intensity. By applying a metallic brush to each supra orbital nerve simultaneously, the Professor banished the original nerve-ache of the left side, and at the same time prevented it from appearing in the opposite one. The same moment, however, a humming noise arose in each ear, and this also immediately ceased on the brushes being removed, when the nerve-ache returned immediately, though in a very mitigated form.

In order to obtain the desired effect from the use of the anodyne brushes, Professor Von Hildenbrand impresses the necessity of determining, as accurately as possible, the nature of the *neuralgia*, or the pathological state of the affected nerve. If the pain is merely *nervous*, that is, proceeding from subversion of the equilibrium between the *dynamic factors of the sensitive life*, as the Professor, in imitation of his father, expresses it, without material changes having taken place in the affected part—in which case it attacks periodically, like an

intermittent disease, and leaves intermissions entirely void of pain,—then the efficacy of the metallic brush may be pronounced to be almost infallible. But if, from the pain being uninterrupted, or at least void of perfect intermissions—from its aggravation under pressure of the part, from the conjunction of redness, heat, or swelling—there is reason to believe that the proximate cause of any case of facial neuralgia or hemicrania, consists in a state of active congestion, or sub-inflammatory irritation,—then the metallic brush affords no benefit, nay, sometimes may augment the intensity of the pain. By these means Professor Hildenbrand thinks that the metallic brush, while it maintains at least a palliative therapeutic property in neuralgia of spasmodic character, may, in doubtful cases, furnish an auxiliary diagnostic sign, by the aid of which sub-inflammatory congestion may be distinguished from simple nervous erethism.

In the first experiments performed by Professor Hildenbrand, he employed brushes which were intentionally constructed of two kinds of metal, for instance, silver and copper wire, copper wire and zinc wire, or zinc wire and brass wire, the individual wires being mutually mingled and blended, on the supposition that electricity or galvanism, evolved by the contact of heterogeneous metals, might be the beneficial and sanative agent. He afterwards ascertained, however, that bundles of wires of one and the same metal produced an effect scarcely less speedy, but lost their anodyne influence as soon as they were covered by rust or verdigris. He further ascertained, that solid metallic bodies produce analogous effects, but in a much feebler degree than the numerous acuminate points of the bundle consisting of metallic wires. The nature of the metal, he adds, seems to cause no difference; for brushes of iron wire produce the anticipated alleviation in as great a degree as those of copper wire. If he could trust his observations, however, he thinks that he perceived a greater degree of anodyne virtue in copper, iron, and gold, than in other metals.

Admitting that the effect is constant, to explain the theory of its production Professor Hildenbrand does not hesitate to deduce it from the laws of electricity. The original nature of metallic bodies, which are remarkably good conductors of electricity; the rapid action of the brush, if the aching spot has been previously moistened by the saline solution; the remarkable tendency of pointed bodies in attracting electricity; and the sense of an emanation, and an agreeable coolness, combined with manifest alleviation of pain admitted by the patients, he regards

as no trifling arguments to infer, in the disordered and aching nerves, a certain degree of *electric plethora*, or accumulation of animal electricity, which may be discharged by the application of a suitable conductor. This hypothesis, he lastly remarks, would accurately correspond with the notions delivered in his elements on the accumulation of the imponderable Biotic principle in various parts of the nervous system, as the proximate cause of nervous disorders which attack in paroxysms, and are dissipated by what he denominates *autoeratic explosions* *.

ROYAL INSTITUTION.

Friday, April 19.

Origin of the Egyptian Worship of Animals.

THE evening meetings were resumed (after the Easter recess) with a lecture by the Marquis Spineto, on Egyptian hieroglyphics. He confined himself principally to those hieroglyphics and pictorial representations which were employed to express the Deity and his attributes. Numerous as would seem the deities of Egypt, they all appear to have originated in the primitive idea of one God. The several forms given to the original figure could all be explained by shewing that they were adopted as expressive of the attributes of the Divine Being. Hence the successive additions of the ram's head, the crocodile's, and the bull's; as well as the female breasts, &c. &c. The Marquis made several interesting digressions in treating of the manners and customs of the ancient Egyptians. He even touched upon their diseases, and hazarded an opinion that Cleopatra's native troops, or body guard, so indignantly noticed by Horace, were wretches afflicted with elephantiasis. We must say that we cannot agree with him on that matter.

New construction of Paddle Wheels.

Captain Basil Hall called the attention of the meeting, for a few minutes, to an ingenious contrivance which he was deputed to explain. This was a form of paddle wheel, so managed as, by means of cranks, to enable the paddles always to meet the water perpendicularly, and thus economize very materially the power of the engine. The inventor of this method is, we understand, a Mr. Grant, an army baker, who declines to take out a patent for it, though strongly advised to do so by several men of science.

* From the Edinburgh Medical and Surgical Journal.

HOTEL DIEU.

CASE OF STRANGULATION — DEATH — AUTOPSY: WITH REMARKS,

BY M. DUPUYTREN.

THE subject of the present case was a female, aged 30, rather tall, and of a sufficiently healthy appearance. She was taken into the hospital on the 20th of last month (March), under circumstances to be presently related. A peculiar wildness of aspect, and a restlessness, were observed in her during the last few days. At four this morning the sister visited her, gave her something to drink, and finding her calm, retired. At five she came to her again: the patient lay on her right side, with her head hanging out of bed; she was insensible, motionless, lifeless! She had strangled herself with a silk handkerchief.

This has been the second suicide committed in the same ward within a week; another woman having, but a few days since, hung herself with the cord suspended over her bed.

It appeared, upon a sort of inquest which was held to inquire into the circumstances, that the female who strangled herself so quietly had been brought up in a convent, but she was seduced, and exhibited latterly symptoms of decided mental aberration.

M. Dupuytren made some remarks on the post-mortem appearances. The mark of the ligature round the neck was deep, ecchymosed, and partially excoriated. The brain, though a little vascular, was healthy; the organs in the thoracic and abdominal cavity presented scarcely any signs of inflammation; the great intestine was filled with hard fecal matter. The other viscera exhibited nothing anomalous.

It is worth observing, that the band with which she tied the fatal ligature was deprived of four of its fingers; so that she must have used much address and determination.

M. Dupuytren introduced some observations on the circumstances by which we might be enabled to determine, in obscure cases, whether death has been the result of apoplexy, asphyxia, strangling, or assassination. He laid much stress upon the moral evidence, and, as to the physical, he thought that strong proofs were generally afforded by the posture and features of the deceased. Death in strangulation, he said, was not produced by apoplexy or cerebral congestion; but simply by interruption of the breathing process, as had been proved by frequent experiment. In hanging, luxation of the vertebrae and injury of the spinal marrow sometimes take place. On

this point there was a controversy about fifty years ago, between the hangmen of Lyons and Paris. The former used to dispatch his victims by luxating their necks, while the latter simply produced asphyxia by compression of the larynx. The Lyons method was the more certain and prompt. M. Dupuytren said he could not conclude without expressing his reprobation of the dangerous practice which some persons have of lifting children up by the head: the slightest motion in the young persons so treated, would suffice to luxate the cervical vertebrae, and deprive them suddenly of life.

MIDDLESEX HOSPITAL.

CASES: WITH REMARKS,

BY MR. ARNOTT*.

It is useful to know not only when to interfere actively or perseveringly, but it is important also to distinguish those cases in which our interference is not merely useless, but may be prejudicial.

Contracted Pupil and Synchysis of Right Eye—Atrophy of the Left.

Joseph S. aet. 20, a tailor, admitted 19th March. By means of the right eye can make his way, and knows objects though he cannot distinguish features. The pupil is irregular, contracted, and occupied by a bluish web of coagulable lymph. The iris, originally blue, is discoloured, has lost its brilliancy, and is of a looser texture than natural. Its pupillary margin is adherent to the lymph just mentioned, and the size of the pupil undergoes no change under the application of the belladonna. The sclerotic, instead of its natural white, is of a dirty straw colour. The globe feels softer than natural. He sees best in a bright light. The eyelids of the left eye are somewhat collapsed; the globe is shrunk to less than a half of its natural size, and feels quite soft. The cornea, small in size, is of an oval form. The iris is completely disorganized, offering no appearance of its natural texture. The pupil is closed by a yellow cataract. Sensibility to light is entirely gone.

This man stated that he was attacked by inflammation in his eyes, first in the right and then in the left, without any evident cause, between three and four years ago. By the treatment then adopted he was somewhat benefitted, but at the end of five months, having got worse, he became an out-patient of the Manchester

* The concluding portion of the Middlesex Hospital Report was *pushed out* last week. The sentence with which the preceding part terminated we re-insert, as it is connected with what follows.

Infirmity, when, among other remedies, mercury was employed so as to affect his mouth, and he so far recovered his sight as to be able to resume his work. Six months afterwards his eyes were again affected, and he became a patient at the Eye Institution for eighteen months, during which his mouth was again made sore, but without permanent advantage. Six or eight months ago his left eye was very large, so that his relations thought it would have burst, but in about six weeks it shrunk to its present size. Having come to London for the express purpose of benefitting his sight, he was received into the hospital for a few weeks, to ascertain if any thing could be done for him. During this time leeches have been applied, and he took decoction of sarsaparilla, with the extract, and five grains of Plummer's pill, at bedtime, but without benefit.

He will be fortunate if he can preserve the sight which remains to him.

Periostitis over the Trochanter—Suppurating Nodes on the Head.

William G., ætat. 30, on presenting his letter of admission, stated that he sought relief for a complaint in his hip, under which he had laboured for the last six months.

He walked lame, and as he stood the right lower extremity seemed longer than the left. On dropping his trousers the right nates appeared flattened; and on placing the hand on the trochanter major, so as to push the head of the thigh-bone against its socket, he cried out from pain. He was sent into Clayton's ward, with the impression that he had disease of the hip; but on examining him there in bed, the case turned out to be different. Grasping the foot so as to force the limb upwards, and thereby the head of the femur against the acetabulum, he did not shrink; he felt no pain. Recurring to that felt on pushing the same parts against each by means of the trochanter, it was discovered that the pain so felt was seated in the trochanter itself; and on examination, a degree of puffiness was perceived on the outside of the part, occasioned apparently by a swelling of the periosteum. Firm pressure on the part gave pain. Attention was now directed to the forehead, which presented a strange appearance, from a degree of prominence amounting to deformity. This was occasioned by a general swelling of the parts over the frontal bone, which, on each side of the mesial line, assumed a more decided character, forming a soft fluctuating tumor; the integuments were of their natural colour, and no pain was felt except on pressure. Under the left eye-brow was a swelling of less size, the skin covering it red, and at one place shewing a yellow point, as if an abscess on the edge of the

orbit was about to break. On the hairy scalp, on the top of the head, were two other soft swellings, of smaller size. No eruptions or cicatrices on the skin of the body; no affection of the throat. Is pale, sallow, and thin. Had a chancre and open bubo seven years ago, for which he took pills eight weeks; never had eruptions or sore throat. Eighteen months ago had swelled testicles, first of the one gland and then of the other, which went down under a pill night and morning for six weeks. Six months ago first felt weakness in his right leg; could not use it so well; and for this he was blistered on the hip, without benefit.

The circumstances of this case, the inflammation and thickening of the periosteum of the trochanter, the nodes proceeding to suppuration of the frontal and parietal bones, with the history given by the patient, pointed clearly enough to a venereal origin. The nodes, indeed, existed as an independent symptom of a constitutional taint; they were not accompanied, and, what is more rare, had not been preceded, by any ulceration of the throat or affection of the skin. But there was one affection which may be considered as connecting that of the bones with the primary sore—that is, the swelling of the testicles. It is true, that this took place a year previous to the first appearance of disease of the periosteum, and that the primary local affection is represented as having occurred six years antecedent to that of the testicles, so that by some they may not be considered as forming a chain of diseased actions arising from the same source; I mean, that it would be denied by some that the disease of the bone and that of the testicle could have arisen from a taint received into the constitution so far back in the one as seven, the other six years previously. Now without being very credulous as to the accounts given by patients upon the subject of venereal affections, I confess I see no particular reason for disbelieving that of this man. He did not declare that he never had any primary sore, but at once acknowledged that he had had, and when; and cross-examination did not invalidate his original statement. Upon the general question too, as to the length of time which may elapse between primary and secondary venereal symptoms, I am disposed to believe that it may, in some instances, very considerably exceed that which is usually allowed. Many surgeons of the present day will not grant you more than a year. I think it may, in some rare cases, extend to several, and I cannot specify the precise limit beyond which we are to say that a particular symptom cannot be considered as syphilitic, and within which it may. I cannot

deny the possibility of the nodes in this individual case having arisen from the chancre which existed seven years previously.

The treatment determined upon was to give mercury cautiously, to produce its effect upon the system, and keep up the action for some time; to combine with it sarsaparilla; to leave the nodes on the head untouched, was to take the chance of their fluid contents becoming absorbed.

Feb. 6th.—Pil. Hydrarg. g. x. nocte, gr. v. mane.

12th.—Mouth affected; some discharge of saliva; pain of trochanter relieved.

Omit the pills; let him have a saline aperient.

14th.—General swelling of the scalp, more especially of the forehead, where the skin is red and shining; slight effusion into the eye-lids. Has been freely purged.

Saline draught, with four grains of Carbonate of Ammonia, and six drops Tinct. Opii, every four hours.

15th.—Much debility. Some bark added to each draught.

19th.—Erysipelas has ceased.

Resume the Pil. Hydr. gr. v. o. n.

23d.—Pil. Hydr. gr. v. mane et vespere; half-diet.

27th.—Mouth tender; pain of trochanter has ceased. The soft fluctuating swellings on the forehead are manifestly less; that beneath the eye-brow has receded. One of those on the top of the head broke about a fortnight ago, and discharged a thin, glairy, puriform fluid; a probe introduced at the aperture in the skin discovered bare bone. This still weeps, but the bone cannot now be felt.

Pil. Hydr. gr. v. nocte; Decoct. Sarsaparillæ, ℥iv., Extr. Sarsap. ℥ss. bis die.

March 24th.—The same remedies have been continued since last report; the gums have been kept tender, to shew the influence of the mercury. The soft swellings on the frontal bone have been gradually removed by absorption, and the whole forehead has now a uniform firm feel. The second swelling on the top of the head broke and discharged for a few days, but the aperture has now been closed for a week. That of the other, which first gave way, has been healed these three weeks, leaving a slight depression at the part. The man is gaining flesh.

April 15th.—The pill and sarsaparilla have been continued until this day. The patient has got stout and strong; and instead of being wan, his complexion is now florid. To be made an out-patient, but to take five grains of pil. hydr. each night for the next fortnight.

This case shews the propriety of not meddling with nodes when they have advanced to suppuration, unless some strong reason calls for it. There was no pain in this case, calling for division of the periosteum, and evacuation of the fluid contents of the swelling. Possibly if those on the forehead had been punctured, they might have proceeded as favourably as did the two on the hairy scalp which broke spontaneously; but they could not have terminated more favourably than they did, and we should have had the disadvantage of scars or marks on the forehead.

What occurred on the top of the head, shews that the existence of bare bone does not necessarily entail exfoliation in these cases, but that the aperture may heal without this taking place.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE CHEST.

—
PERIPNEUMONIA.

HAVING concluded the subject of inflammation of the air tubes, I shall now proceed to speak of inflammation of the air cells.

A large number of cases of inflammation of the lungs are considered to be inflammation of the substance of that organ, but they are in fact nothing more than bronchitis. By far the greater number of instances that we see of inflammation of the lungs, is not inflammation either of the air cells or the cellular membrane, but inflammation of the bronchial tubes; occasionally, however, we have inflammation, as it would appear, of the air cells themselves. This, properly speaking, is *peripneumonia*. The term *pneumonia* is the name given to any inflammation within the chest, even to inflammation of the heart and pericardium; but the word *peripneumonia* is more properly applied to inflammation either of the air cells, or the cellular membrane around them, whichever it may be. I have no doubt, however, that the inflammation is inflammation of the air cells themselves, and it is in this point of view in which I shall now speak of it.

General Symptoms.—The common well-known symptoms of this disease, those which are discernible without the aid of the ear, are very much like those of bronchitis. There is pyrexia, general feverishness; rapidity of respiration; shallow-

ness of respiration; cough, and expectoration. In bronchitis, you will recollect, I mentioned that there is a sense of constriction in the front of the chest, a soreness sometimes pretty considerable in coughing; whereas in *peripneumonia*, if there be any thing, there is rather a deep-seated dull pain, and this is sometimes confined to one spot, yet for the most part this dull uneasiness is pretty much diffused, and, indeed, is frequently so very slight that a diagnosis cannot be universally made from it. Then the dyspnoea, if people lie still, is by many persons scarcely complained of any more than it is in bronchitis. Some persons labouring under bronchitis will not allow that they have difficulty of breathing, neither will they in *peripneumonia*. Just as in bronchitis, there is frequently violent cough, but sometimes there is scarcely any; the cough is infrequent and soft. There is, however, according to Laennec a decided difference in regard to the expectoration; he considers that the expectoration in *peripneumonia* is a pathognomonic distinction, and points out the nature of the disease. He says, when in this disease the sputa are received into a flat and open vessel, they might unite into so viscid and tenacious a mass that we may turn it upside down, even when full, without the sputa being detached, although they may partially hang from the vessel's mouth; but the great bulk still sticks to the vessel. Their tenacity, he says, is such that it makes them vibrate like so much jelly; and the tenacity prevents the air bubbles, which are in great numbers in this kind of sputa, and sometimes very large, from breaking. The air does not escape, but forms bubbles, and be they small or large, for the most part they remain.

I cannot confirm or disprove Laennec's assertion from my own observations; but I think all will allow that we must look beyond the sputa, as well as beyond the general symptoms, for an accurate diag-

nosis of this disease; for Laennec allows that the sputa are frequently not so viscid as all this; he allows that frequently they are of some shade of red or green, though for the most part they are but little coloured; and he allows that frequently they are almost destitute of air bubbles, frequently a mass of mere mucus or pituitous secretion, and a few glutinous, with slightly tawny portions. I cannot, therefore, but think, as he allows all this, that we ought not at all to depend upon the sputa for a diagnosis. Indeed, when the characteristic sputa do occur, as they continually do, it is very often only at the onset of the disease, only for a few hours, and even then sometimes only in so small a quantity as scarcely to admit of being collected.

The pathognomonic signs of this disease are acquirable by the ear only; but before considering them it will be necessary to trace the appearances after death in that region, and the succession of the changes. This is an opposite course to what we usually adopt: generally we speak of *post mortem* appearances when the symptoms are done with, but here it is necessary to reverse the order, for the symptoms are in accordance with the unnatural changes.

Appearances in the First Stage.—In this stage of inflammation of the air cells, the lung merely suffers an accumulation of blood, so that it becomes more solid and heavier than usual; it looks livid externally, and retains the impression of the fingers, like an oedematous limb. On cutting into it, it is found to be of a deep blood colour, and replete with frothy, bloody fluid; but still the lung is spongy, still it crackles under the fingers. This is a stage in which after death you will find nothing but an accumulation of blood and serum.

As the lung crackles after death, as it contains air to the very last, you will expect to hear in these particular parts during life the murmur of respiration, and that is the case; and as air is admitted, you will expect to hear on percussion the usual hollow sound on the chest, and that likewise is the case. But the murmur which you hear when the inflammation has only reached the first stage in that particular part, is accompanied even from the very first moment of the attack with a crackling sound. You have not the ordinary murmur of respiration, but it takes place with a *crepitous rattle*, as it is called, or, if you please, a crepitous respiration. It gives you the idea of numerous minute, and almost dry bubbles, and you hear this dry crackling the more decidedly the nearer the inflammatory spot seems to be to the surface; and those who have employed their ears frequently, can from

practice tell the exact depth of the inflammation, from the loudness of the crackling. The nearer the disease is to the surface the louder it is heard.

Second Stage.—*Hepaticization.*—When the inflammation has become more intense, the lungs are heavy, and they become so firm as to resemble liver, and on this account the term *hepaticization* has been applied to this state, but really, I must say, very absurdly. The lungs are not changed into liver; if they were, it would be hepaticization; but if they only remain as solid as liver, something like liver, it is an improper word. By ossification, we mean an absolute conversion to bone, and by hepaticization we ought to mean a conversion into liver. If a thing is to be named in this way, because it is only like another, strange words might be applied to every thing. Hepaticization merely means that the lungs have become as solid as liver; and Andral proposes another term, *solidification*, which I think better. If the lungs have become solid, solidification is a correct term.

Now in this state, where the lung has become so solidified, it will not crackle under the finger—it has evidently become impervious to the air. If you cut it, squeeze it, and scrape it, very little fluid escapes from it, and what does escape is not frothy, neither is it so thin as that which escapes in the first stage. I presume that in these cases there is more or less fibrine effused or deposited, and that is the explanation of the solidity, the want of air, and the want of frothy fluid.

When the lung has fallen into this condition, you may presume what the symptoms are. On striking that part of the chest where the lung has become so solid, you of course cannot have a hollow sound. There is no air there, as usual, no room for it, but a solid mass, and on striking over it you have the same dead sound as if you struck over the liver. On listening to the part, as it contains no air you of course cannot have the respiratory murmur, and having no murmur there is no respiration—you cannot hear crepitous rattle. In the first instance you have crepitous rattle, because there is a thin fluid in the air cells; but here there is no thin fluid in the cells—they are all solidified, and therefore there is no crepitous respiration. If, however, the part happen to be situated near a large bronchial tube, you will hear the patient's voice there, on account of solids being better conductors of sound than aeriform bodies.

Third Stage.—Before death, however, a still further change will take place. Inflammation of the lungs tends to suppuration, and at an advanced period a third

stage occurs; but there is this peculiarity in supuration of the lungs—the pus is diffused, and not collected into an abscess. After the second stage, when the third begins, the lung is as hard as before, but it becomes yellowish, or of a straw colour. When the pus is first formed in a small quantity, there is quite sufficient to change the colour of the lung; but after a little time the pus becomes more abundant, the lung becomes soft, and will yield to the point of the finger.

In this stage, just as in the second, there is no hollow sound on striking the chest, neither is there any respiratory murmur, but a loud mucous rattle—that rattle which I stated you may have an idea of, by recollecting the sound occasioned by air passing through soap-suds. The mucous rattle is heard in the bronchiæ, either from some of the pus going into them, or a secretion from their own membranes.

Abscesses in the Lungs.—Should, however, an abscess be formed, should the pus be collected into a mass, a characteristic symptom will be heard, such as I shall mention under the head of phthisis. But such an occurrence is extremely rare: I do not recollect above twice seeing an abscess in the lungs, great or small, resulting from inflammation, and when I did see them they were small and full, and just as likely to be the result of a few distinct tubercles, which had existed in the lungs previously to the inflammation, as of inflammation itself. Some persons will have an odd tubercle or two formed in the lungs, without inflammation—that we see continually—and these may suppurate, and an abscess be formed, and if the lung fall into a state of inflammation, the solitary abscess may be ascribed to inflammation. So rarely is it the result of common inflammation of the lung, that I have only seen it, I am sure, once or twice, and then I cannot be certain that it was the result of inflammation, and not the result of previous tubercles. When abscesses do occur in the lung, I am satisfied that Laennec is right in asserting that they are almost always occasioned by the softening of tubercular deposition, the softening of serofulous deposit. Among several hundred dissections of peripneumonic subjects, says Laennec, I have not met with a collection of pus in an inflamed lung more than five or six times. These were not of large extent, nor numerous in the same lung. Even Broussais, to whom Laennec was in many points indebted, declares that he never saw ulceration in the lungs, without tubercles, more than once, and then the inflammation resulted from a musket-ball, which was tantamount to a tubercle. The reason assigned by Laennec for the circum-

stance is, that the disease is cured by art, or destroys life before it proceeds to the length of destroying the pulmonary tissue; that death takes place before the disease advances so far as for matter to be formed in the lung in an abscess. This disease is frequently fatal when it is not of great extent, when it has not passed the first of the three stages to which I have alluded.

The first and the second of these stages are frequently seen in different parts of the same lung, and you may even see the third stage. You observe one stage going into another.

It is very remarkable that in the greater number of instances the inflammation commences at the lower part of the organ, and it may not extend higher; and when the disease has advanced, it is consequently in the lower part that the second or third stage is generally found, while higher up the disease may only be in the first stage, or be entirely absent. The right lung, it has been asserted, is more frequently affected than the left: of that I cannot speak, but I can speak to the fact of inflammation, in an infinitely greater number of instances, beginning at the lower part of the organ than higher up. There can be no doubt that the membranes of the air cells, and not the surrounding cellular tissue, is the seat of the disease. In the second stage of the disease, when the lung is solidified, but still red, if the structure be cut or torn, instead of the natural appearance of the cells, the inflamed part has minute granules, round or oval, corresponding exactly with the appearance which the air cells would give, if filled with a tenacious fluid, and solidified; and, indeed, Louis found that, by forcing fluid into the bronchiæ, the same granular appearance might be produced by art, and therefore this granular appearance clearly arises from the air cells being filled with the same tenacious fluid. The crepitous or crackling rattle also shews, I think, the same thing, for it is heard in another affection, in which this thick fluid evidently exists in the air cells. In hæmoptysis, when bleeding takes place in the air cells, the same sound is heard as in peripneumonia. Now in hæmoptysis this must arise from little bubbles snapping and cracking through this fluid, and as the same sound precisely is heard in peripneumonia, I think it is a strong argument to prove that the air cells are affected by the disease, more especially when we see that a certain peculiar fluid is spit up in the affection.

Those rare cases of inflammation of the lungs which end in the existence of abscess, are marked by the same auscultatory phenomena as occur when there is a phthisical

excavation. You hear the sound come through the tube; and when the patient breathes there is the sound of a cavity, and there is a metallic tinkling, of which I shall hereafter speak—a noise as if a bell were struck with the point of a pin, or something very fine.

Inverse progress of the stages, when the Affection is remedied.—Now if, by art, the disease be remedied—if the inflammation yield—of course the lung goes through the same stages as before, but inversely—the third stage comes to the second, and the second to the first; and it is found that the signs, audibly noticed by the ear, go through the very same inverted course: the auscultatory phenomena heard in the second stage disappear, and those which occurred in the first stage are heard again. Nothing is more interesting, certainly, than to trace the reversed order of the changes here. Suppose the disease has only gone into the first stage, you hear the hollow sound on striking as in health, and, on listening, you hear crepitous rattle, and even crackling. You cure the patient; and, as he is being cured, the crepitous rattle declines—it becomes fainter and fainter every day—and instead of that you have the natural murmur of respiration more and more distinct. Suppose the second stage has been reached, and you are successful; in that case the want of a hollow sound, on striking the chest, gives way, and you hear by degrees a little hollowness of sound—and you hear it more and more every day, till that side of the chest sounds as hollow as the other. The respiration had ceased from the lungs having become solid; but you hear a little crepitous rattle increasing every day till you hear it as distinct as in the first stage; and then, having arrived at the first stage, the disease passes through that entirely; you hear the crepitous rattle decline, and you have the natural respiratory murmur becoming more and more distinct. I mentioned that, in the third stage, you still have no hollow sound, but you have a mucous rattle, generally from the entrance of pus into the bronchial tubes. This declines by degrees, if the patient get better, and then you gradually hear a crepitous rattle, from the cells losing a part of their viscid contents, so that they again admit a portion of air. The chest then regains its hollow sound on striking, and at last the crepitous rattle declines. Anatomical examination shews the changes of the part to be precisely correspondent with these auscultatory phenomena. When the first stage is recovered from, the lung is found to grow less red, less turgid. Supposing the patient dies from intense inflammation of one part of the lungs, there is a lower

degree in another part, and you find that is only in the first stage; but you are still able to make your observations there. You find perhaps that you have cured the inflammation at that one spot—that respiration is heard there more and more, while in another part it is heard less and less; but the patient dies, and, by examining different parts of the lungs after death, and having listened to them through life, you are able to trace the changes. When the inflammation of the third stage is being recovered from, the lung becomes less turbid; and when the second stage is being recovered from, back to the first, the colour also becomes less intense; the texture becomes softer; the weight decreases; the organ, on comparison, affords more fluid; the fluid becomes more and more of a frothy character; and the granular appearance declines. In the second stage, I mentioned there was a considerable granular appearance; now this granular appearance declines, and the vesicular character of the lung returns. When the third stage is recovered from, the yellow colour becomes lighter and lighter; the pus becomes more aqueous, less thick, and at length it becomes frothy, and the accumulations of pus are reduced to mere specks; the vesicular appearance returns; the lung crepitates, and at length grows natural; and the little serous infiltration that there was is absorbed.

Importance of attending to the Auscultatory Phenomena.—Notwithstanding cases of peripneumonia are every day recognised, and the amendment or exasperation of the disease is ascertained by practitioners who never employ their ears—as though nature had given us ears to be used on every occasion except when we are practising our profession—although the disease has been well known, and increased intensity or improvement ascertained very well without the aid of the ear, yet the observation of the auscultatory signs in the three stages of peripneumonia is sometimes more than a philosophical observation—more than an intellectual gratification. Many cases of inflammation of the lungs, I know, have been overlooked in the midst of other diseases, or have been totally mistaken. It is in vain for those who obstinately refuse to avail themselves of the means given us by nature in the sense of hearing to learn the phenomena of disease, to assert that they can form an accurate diagnosis on all occasions; because these persons are lamenting that medical evidence is uncertain, and, to my certain knowledge, they do perpetually mistake diseases of the lungs for diseases of the heart, and diseases of the heart for diseases of the lungs; and in the affection before us, peripneumonia, if it suddenly supervene during a chronic affection

of the chest, they continually ascribe the symptoms to effusion, to pleuritis, to dropsy of the chest coming on, or something else, having no idea whatever of the real disease. In phthisis, an aggravation of the dyspnoea, unattended by pain, is very common, and is ascribed to an effusion into the chest, or the bronchia, or the substance of the lungs; and in chronic bronchitis it is ascribed to an attack of spasmodic asthma; when the simple trouble of listening to the lungs would shew crepitous rattle, and that the difficulty of breathing arose from the presence of peripneumonia. In various fevers, eruptive and simple, in simple dyspnoea, without pain, during an attack of rheumatism and of gout, peripneumonia is continually overlooked; and some surgeons have stated, that, after severe wounds and operations, peripneumonia will occur in the most insidious manner, and not be discovered till all possibility of remedy is over. Surgeons have lost patients under operations, after having suffered severe accidents, without knowing why; and, after death, they have discovered that the lungs have been inflamed. This is a fact that you will find mentioned in many surgical books. All this mischief will be prevented by examining the chest with the ear in every instance of dyspnoea whatever,—where there are no pectoral symptoms at all—no signs of any morbid affection of the chest,—but where pectoral complaints are likely to supervene. This may be avoided by examining the chest from time to time, exactly as we feel it to be our duty, on other occasions, to ascertain not only the state of affected parts, but the state of the head, and of the abdomen.

Causes—As to the causes of this disease, they are those of any other inflammation. I did not speak of the causes of bronchitis, because in both diseases they are the same. Cold is a common cause; vicissitudes of temperature; cold and heat, applied in the way which I mentioned when speaking of inflammation. Both bronchitis and peripneumonia supervene on other affections of the chest. It is common, in diseases of the heart, for persons to be seized with one or the other, either in an acute or chronic form. Nothing is more common than to see bronchitis and peripneumonia united with diseases of the heart and pericardium; and so nothing is more common, in diseases of the lungs, than to see these affections. In phthisis we have bronchitis, acute and chronic, and peripneumonia; and so in every other disease of the chest. Inflammation is frequently idiopathic, arises from a common cause; but sometimes it is symptomatic—is the mere result of another disease in the neighbourhood.

Treatment.—As to the treatment of the disease I shall not dwell a moment upon

it; it is only the treatment of any inflammation. Patients have sometimes borne the loss of an immense quantity of blood; perhaps more in this disease than in most others. It is in this affection that those enormous bleedings are reported to have taken place which I mentioned when speaking of inflammation in general—a few gallons in the course of a few days. I have no experience of such bleedings as these. Mercury is of the same use in this affection as in bronchitis, and in bronchitis as in other inflammatory diseases.

GANGRENE OF THE LUNGS.

You might suppose that if the lungs ever became gangrenous, it would be the result of inflammation, as gangrene so frequently is in other parts of the body; but I believe that the severest inflammation of the lungs seldom, if ever, induces mortification. Sometimes it may be the case, but it is so rare that I myself have never seen it. The lungs will fall into a gangrenous state, and there is more or less inflammation attending it; but the gangrene does not appear to be the result of the inflammation; on the contrary, indeed, when nature makes an attempt to get rid of a gangrenous spot, inflammation is induced all around, in order to discharge it—so that the inflammation is sometimes the result of gangrene.

In my own practice I have only seen two cases of this disease, and which were of a different kind, and completely illustrated what Laennec has advanced on the subject. On some points Laennec has brought our knowledge to perfection: in some cases nothing has been done since his time, and perhaps nothing will be done. In one of these cases in my own practice the gangrenous part was unencircumscribed. A large part of the lung was of an unnatural colour—dark greenish, moist, and soft, and in some spots it was a mere putrid pulp, little more than so much mud, and of an insupportable odour. In those parts of the lung which I saw, that were not in a gangrenous state, the organ was firm, of a chocolate colour, or a deep green. These appeared to be the three stages of the complaint. There was one part a chocolate colour or deep green, indeed quite firm; another part was moist and soft, and of a dark green; and the third part formed a perfectly putrid, soft, muddy mass. A large portion of each lung was in this condition—in one of the three stages of this affection. In another case that I had, the gangrene was in more circumscribed patches or spots. There were patches of the lung, black, soft, moist, and offensive in the worst spots; and in other parts, where the lung was still firm, it was of a green hue. No attempt, in this latter

case of mine, had been made by nature to effect separation; but Laennec mentions, that a gangrenous piece sometimes detaches itself, or is detached from the surrounding parts, just like a slough from caustic. That is an apt illustration of the appearance; because although the patches in my case were not separated, yet, if they had been, such would have been the state. The gangrenous part becomes dry and shrivelled, just like a spot to which caustic has been applied, or it degenerates into a putrid paste like mud. The surrounding structure is inflamed, as in other parts of the body when nature attempts a separation. You know that when a dead part is separated from the living by inflammation, that inflammation ends in ulceration, so that the dead part is left without any connexion with the living. The living part disconnects itself; the dead part becomes isolated, and is afterwards separated. If nature succeed, as she does sometimes, a cavity is often found where the gangrene existed, and the cavity has a lining membrane. Sometimes no cavity is left, but a cicatrix is formed, and the whole appears to have grown up together. This appearance has been perfectly well described by Laennec, and by others. In some instances the separated portion makes its way into the pleura, and pleuritis is induced; and pleurisy, with its effusion, and pneumothorax, are the consequences.

In my two cases, the disease was marked by a sudden prostration of strength, and a cadaverous alteration of the face; great feebleness of pulse; and an intolerable fœtor of the breath and sputa. One of these cases occurred in a man who had long suffered from a loud hollow cough, with a copious frothy expectoration; the other occurred in a woman who laboured under an encysted tumor of the pancreas. In her case a slight cough came on, which attracted no attention, and at last symptoms of gangrene appeared. These general signs will point out the disease, I imagine, much more than auscultation; but it is evident, that the gangrenous part must have less respiratory murmur than natural; the part around will afford crepitous rattle, and the cavity will give rise to pectoriloquy. If inflammation be set up for the removal of the slough, causing the bronchial tubes to be affected, there will be a metallic tinkling; but I imagine that far better evidence than this will be derived from the aspect of the patient; from the cadaverous look, and the great debility, together with the intolerable stench both of the breath and sputa.

Symptoms.—When a part has become gangrenous, of course there is no hollow sound on striking, and no respiratory murmur; but that may arise from ten thousand

things, and if there be any inflammation around the dead part set up to cause its separation, there will be a crepitous rattle, but no one could tell that this resulted from gangrene rather than from any thing else. There are, however, certain signs observable by the other senses, which alone would make you believe there was gangrene; and those, together with the stethoscopic signs, make the thing pretty certain. The sputa, sometimes in this disease, are at first white and opaque; but they grow sanious, purulent, brown, and greenish, and they are from the first nearly as fœtid as when the fœtor becomes gangrenous. We all know the fœtor of a gangrenous part; and before the sputa have that peculiar fœtor, they are nevertheless fœtid enough: but this cannot be much depended upon, nor can the fœtor of the breath. I have seen other diseases attended with extreme fœtor, but without gangrene; and I have seen extreme fœtor of the breath and sputa without any danger whatever. Sometimes, in bronchitis, the fœtor both of the breath and sputa will be extreme. I mentioned having seen a young lady who was in tolerable good health, except that she spit up a little, which was horribly offensive, and to stand near her was extremely unpleasant; yet she was walking about, and looking well. I saw a case of this fœtor of the sputa and smelling of the breath in a person who died of phthisis. Occasionally the matter formed in phthisis is of such a quality that the fœtor is much like that of the fœces. There is no danger *necessarily* from the extreme fœtor of the sputa, neither is there necessarily gangrene; but if, conjoined with this, you observe they are bloody, brownish, greenish, something like the discharge from a sloughing part—when you observe any thing like little green fragments of lymph with it, a weak pulse, an elongated countenance, and a cadaverous aspect, and the patient in the state in which you see people when they are sinking from mortification in any part, then there can be no doubt of the nature of the disease. But the mere putrid smell of the breath, and of the sputa, certainly ought not to make you conclude that the patient must have gangrene of the lung, or, indeed, be in any danger. In the two cases of this disease which I had under my care, the persons became in a few days very much emaciated; the pulse suddenly fell; the temperature declined; and the countenance expressed the most extreme exhaustion; but at the same time I must honestly tell you, that I had no idea in either case of gangrene in the lungs, and was much struck after death with the appearance, and then I could compare it with the symptoms I observed during life. One patient had merely chronic bronchitis for a long time,

which appeared sufficient to kill him; and the other was dying of disease of the abdomen, and complained of a trifling cough, which had not attracted my attention. They were hospital patients; and it was only when opening them that I discovered the disease. I smelt something very horrible when near them, but I ascribed it to another cause.

Not necessarily fatal.—When gangrene does exist in the lungs it is not necessarily fatal. There have been cases clearly of gangrene of the lungs which have been recovered from, when all these symptoms occurred. Nature is sometimes sufficient, when supported by good nourishment, to get an individual through an affection of this description, and to cause a separation of the gangrenous part.

Treatment.—In regard to the treatment, there can be nothing peculiar; you must support the strength of the patient as in other cases, where there is an absence of inflammation, and the presence of extreme debility.

HÆMORRHAGE FROM THE AIR-PASSAGES.

There is another disease of the substance of the lungs, and of the membrane of the air cells, which after death presents very much the appearance of inflammation, and was frequently, no doubt, before the time of Laennec, mistaken for inflammation. This disease is the effusion of blood into the air cells, and I shall now therefore speak of hæmorrhage from the air passages, which will be in conformity with the plan I have hitherto pursued; viz. that of speaking first of inflammation, and then of certain other affections, among which is hæmorrhage.

From the Air Passages.

Character.—It may proceed from the mucous membrane of the air passages, or from the air cells. In the one instance, it is not necessarily a dangerous disease; in the other it is highly dangerous, in as far as it is likely to be very profuse; but the greater number of cases of hæmorrhage from the air passages arise simply from an effusion of blood from the mucous membrane of the bronchial tubes. The blood which is spit up is florid, generally of a bright scarlet colour, and frothy. It is spit up with a tickling in the throat, the pulse is quick, and there is heat in the chest. This is the description of hæmorrhage which takes place most frequently in young adults, between the age of puberty and the full adult period of five-and-thirty. It occurs particularly in that period during which the chest expands—in which we spread, as they say. The first part of life

is disposed to hæmorrhage from the nostrils; the second to hæmorrhage from the lungs; and the third to hæmorrhage from the abdomen.

Diagnosis.—The disease, in general, is easily made out; the only difficulty is to distinguish between it and hæmorrhage from the stomach; but the latter is usually marked by a discharge of black blood—the blood is either discharged from the veins of the stomach, or it lies in the stomach so long after its escape from the vessels that it acquires a venous hue. From the one circumstance or from the other, blood, when discharged upwards from the stomach, is generally black, and has generally lain there long enough to be coagulated; it is in clots, larger or smaller. It frequently, too, appears in the fæces; it passes through the pylorus, and you see it in the motions. Besides that, it frequently comes up with the food—with the contents of the stomach; and, when it does not, still it comes up with sickness and nausea, if not with downright vomiting. You know that people will have a discharge from the stomach without vomiting. Sometimes a quantity of fluid comes to the mouth, and even portions of food come up without vomiting; and so it is with this blood—but occasionally it comes up with decided vomiting. There is frequently a great uneasiness about the præcordia, and a fulness about the liver and stomach. These symptoms are all absent in hæmorrhage from the lungs. The blood, too, is florid; and, instead of being mixed with food, it is frothy, and is necessarily mixed with air, in consequence of the parts from which it comes. These parts will not allow it to stay so long as the stomach, and it generally comes up as soon as it is poured into the passages, and therefore seldom comes up coagulated. Occasionally, however, you see a little coagulum; it will lie sometimes sufficiently long to become solid and black before it comes up. Then, in addition to this, you have pectoral symptoms. In the stead of nausea and vomiting, you have stitch in the side, a little cough, and a tickling in the throat.

This species of hæmorrhage occurs more particularly in those persons disposed to consumption, with a fine soft skin, soft hair, and of a sanguineous temperament; and, among these, it occurs more particularly in those who have a florid colour. The disease sometimes occurs in those who have evident signs of inflammation; sometimes it occurs where there is hardly any thing at all to be perceived; and sometimes it occurs in those in whom there appears to be great strength of system.

Causes.—It is produced by all the causes of inflammation. A blow on the chest, or catching cold, will give rise to it; but it

very often takes place without any exciting cause. Occasionally, violent exercise, and excitement of mind or body in any way, will produce it; but sometimes it occurs without any apparent cause. It will return at certain periods, at intervals of a month or a twelvemonth, and at last it will cease altogether, and the patient will then become the subject of consumption. It is very common for consumption to take place in patients who have had several attacks of spitting of blood; but this is not a necessary occurrence. I know many persons who spat blood fifteen or twenty years ago, and they are now as well as I am. If a person spit blood, he should avoid every thing which causes an irritation of the chest, but he ought not to condemn himself; for I have known persons spit a considerable quantity again and again, and yet afterwards do perfectly well. If you listen to the chest when the blood is in the air-passages, you will hear sibilous and sonorous rattle.

Morbid Appearances.—When these patients die, and you examine them, you find nothing at all. If you examine a person who has died of phthisis, and who spat blood before there were marks of phthisis, there is nothing to account for the hæmorrhage. It is a mere effusion from the mucous membrane, which will pour out blood without a rupture of the large vessels, and even small ones will throw out a gush of blood. When speaking of hæmorrhage in general I mentioned, that you will open persons who have died of hæmorrhage from the stomach and intestines without being able to find a vessel ruptured; it was clearly an effusion from a thousand minute orifices.

From the Air-Cells.

Sometimes, however, hæmorrhage from the lungs is not of this description—does not take place from the mucous membrane; it is a particular disease occurring in the air-cells; and in that case the hæmorrhage is generally very profuse, far more profuse than in other cases.

Morbid Appearances.—On examining patients after death, (for they frequently die of it,) you find certain parts of the lung become exceedingly hard, and, if they be near the surface, you see the lung through the pleura very dark. The lung looks variegated, and there are large black patches here and there. If they be deep in the substance of the lung you cannot discover the extent, but, on taking hold of the lung, you feel hard patches, some as large as nuts, some as large as walnuts; and, on cutting into them, you find they are exceedingly red, of a deep colour, and no doubt formerly they have been mistaken for so many large circumscribed inflammations. These parts of the lung may be from one to four

cubic inches in extent, and even much larger than that, and the redness is a deep damask hue; nay, it is sometimes so intense as to be black—as dark as a black clot of blood. This portion of the lung is, of course, not only hard but heavy, and it will not crackle under the finger.

On cutting a portion of the lung in this condition, you observe the same granular appearance which I stated took place in inflammation of the substance of the lungs. In inflammation of the air-cells, before the part is completely solidified it has a granular appearance, which no doubt arises from blood being effused into the air-cells, and there coagulating. The blood coagulates in each air-cell; the minute coagulum of each cell becomes a little grain, and furnishes this granular appearance. The parts are usually perfectly circumscribed, so that the surrounding portion of the lung is in every respect healthy. In inflammation of the substance of the lung, the diseased appearance is gradually lost in the healthy lung; but in this disease, in almost every instance, the affection is entirely circumscribed, so that within a hair's breadth of it, I might almost say, the lung is perfectly healthy. The case is really one of severe ecchymosis, only that the blood is not effused into the cellular membrane as in ecchymosis of the surface of the body, but is effused into the air-cells. That the blood is effused into the air-cells, and not into the cellular membrane, is, I mentioned, proved from the circumstance that the blood is spit up. If the blood were not in the air-cells, but in the cellular membrane, it could not be spit up.

Symptoms.—But the great symptom of this affection during life is hæmorrhage—*hæmoptysis*, as the disease is called, spitting of blood; and that necessarily shews that the blood has escaped into the air-cells themselves. Besides the symptom of repeated and copious hæmorrhage, there is cough; difficulty of breathing; heat in the front of the chest; flushing in the face, and at length great paleness of it; and a tickling sensation in the bronchiæ, just as when hæmorrhage comes from the other source. You cannot tell whether the blood comes from the mucous membrane or the air cells by any of the general symptoms, except that, when it is effused in a very large quantity, there is a probability that it comes from the air cells. It is said that as much as ten pints of blood have been discharged from the lungs in this way in forty-eight hours; and Laennec says that he has seen thirty pints thus spit up in fifteen days.

May exist without Hæmorrhage.—Now the disease may exist in so slight a manner that no hæmorrhage takes place. I have known this state occur without hæmor-

rhage. The blood has been effused into the air-cells, and coagulated there, and produced these bumps; and not having been followed by subsequent attacks, none has been expectorated; and old persons have died from other diseases, who were not known to spit up blood at all, but in whom this appearance was found.

Impropriety of calling it Pulmonary Apoplexy.—From the appearance, Laennec has termed this disease *pulmonary apoplexy*. As this lesion evidently results from sanguineous exhalation into the air-cells, and perfectly resembles the cerebral sanguineous exhalations which produce apoplexy, he has thought it right to designate it “pulmonary apoplexy.” Now I think you will agree with me that this is an exceedingly absurd name. So far as there is a great local congestion of blood and effusion, the phenomena are the same as are observed occasionally in apoplexy. But apoplexy is not a state of the parts; it is a loss of sense and motion, occurring, for the most part, suddenly: apoplexy is a stroke that causes persons to fall down senseless and motionless. In the words of Cullen, “*Motus voluntarii fere omnes inminuti, cum sopore, plus minus profundo, superstite motu cordis et arteriarum.*” That is what we mean by apoplexy. If a person be said to have apoplexy, and you ask the individual how he knows it, the answer is, “He has lost all sensation and power of motion. He is without sensation, and without motion; there he lies in a dead state, and you cannot arouse him.” The morbid state of the brain is not apoplexy, but the symptoms which we observe; and those symptoms will take place from the depression of a portion of bone, or from an effusion of water. Any thing which compresses the brain will produce, not congestion of blood, but a loss of sense and motion. Nothing of this kind, however, occurs here. There is no loss of sense or motion in this disease, and therefore it cannot be apoplexy. But merely because apoplectic symptoms arise from a congestion of blood or hæmorrhage into the brain, Laennec has thought proper to call this state of the lung “apoplexy.” Apoplexy will frequently arise from a secretion of pus pressing upon the brain, or a secretion of mere serum, without any congestion, without any fulness of the vessels; as in the case of a part becoming ossified, so that it splits across, and allows the blood to escape into the brain. Thus you may have hæmorrhage without apoplexy, and you may have apoplexy without congestion—without any hæmorrhage. I cannot, therefore, but think, that it is an extreme abuse of terms, and likely to cause great confusion, to call this disease apoplexy of the lungs; for there is no resemblance whatever between it and apoplexy, properly so denominated.

This disease has not been known a long period. Dr. Forbes, in his translation of Laennec, mentions, in a note, that, “in 1816, M. Lévillé appears to have read a memoir on this subject before the Academy of Sciences at Paris; and, in 1817, Dr. Hohnbaum, of Hildburghausen, published three cases of sudden and fatal effusion into the substance of the lungs.” He says, the lungs were found distended with dark-coloured blood, partly coagulated and partly fluid, and were almost too large for the chest. In one case the same kind of blood was found in the bronchiæ, and in the other in the pleuræ. The cases appeared to be nothing more than a laceration of the blood-vessels; and the patients appeared to die between the effects of internal hæmorrhage and oppression of the lungs, induced by the effusion of blood—to die of syncope and asphyxia. Dr. Forbes described such a case formerly in his translation of Avenbrugger. From the suddenness with which it occurred, and it appearing to arise from a laceration of the vessels of the lung, producing congestion, Dr. Hohnbaum gave the name of pulmonary apoplexy to this particular case. But we must consider that neither sudden death nor effusion constitute apoplexy; for apoplexy is nothing more than a loss of sense and motion. In apoplexy the motion of the heart may continue, but volition has ceased partially or entirely in the brain. There can be no doubt, however, that Laennec was the first on the Continent who gave a full and accurate account of the disease, which he did in 1819. The disease was really not understood fully till Laennec wrote upon it at that time; and he then pointed out the common connexion of this particular state of the parts, with profuse hæmoptysis. Yet it is singular, and you will excuse me mentioning it, that I myself published an account of this affection (there was no merit in it), and gave the appearances after death, and the symptoms during life, some two or three years before that. I had a patient die of profuse hæmoptysis, which I could not stop. I stopped it for a time, but it came on again and again, and, as he sank, I examined him after death, and I found to my astonishment the appearances of the lung which I have described to you. I found on the surface of the lungs, numerous hard, circumscribed, dark patches; and, on cutting into them, I found hard solid lumps, of a deep chocolate colour, there being many of them in the lungs. I cut them into slices, and found they admitted the light through them, just as a clot of blood will do if you cut it very fine.

The case was that of J. G., aged 35, (and it will shew the course of the disease very well,) by business a gardener, a mild and

extremely steady man. He had laboured for two years under dyspnoea, pyrexia, cough, pain of the chest, bloody expectoration, and, at length, profuse hæmoptysis. Various remedies were prescribed, but in vain; and he ultimately died exhausted. On opening the body, the surface of the lungs presented numerous hard, circumscribed, very dark patches, of various sizes, from that of a sixpence to the size of a crown. A person not of the profession would have supposed them so many mortifications. Blood, however, when accumulated in the small vessels, often causes a counterfeit appearance of mortification in the stomach and intestines, as Dr. Baillie has pointed out, and in many other parts. Such was the nature of these patches. On cutting perpendicularly through them, the hardness and dark colour were found extending inwardly an inch or less, equally circumscribed as on the surface. The intervening spaces were perfectly healthy. This Laennec also remarked. Nearly the whole of the inferior lobe of the right side had undergone the same change as the circumscribed portions in the other lobes. This change consisted in a prodigious congestion of blood, which gave the dark colour and hardness, but which could not be squeezed out at all. The slices were quite diaphanous, and of a beautiful red. No other change, no disorganization, was in any part discernible. It seemed as if the most minute vessels in various parts had become dilated, as in *nævi materni*, and thus allowed the escape of the blood. Had the symptoms been those of acute inflammation, and the blackness not been in detached portions, there would have been nothing singular; and had the disease been simply chronic inflammation, which a frequent pain at the anterior and lower part of the chest, always yielding to blisters, and a large quantity of bloody fluid in the cavities of both pleuræ after death, argues, yet it is surprising that this should occur in patches, and should have induced no suppuration, no disorganization, but merely hæmoptysis and pain.

Of course there was no great discovery in it. I opened the man, and the appearances were provided for me, and I described them. I pride myself on one thing, that I did not call it apoplexy of the lungs. I gave it no name. The work in which the case was published, was called the "*Annals of Medicine and Surgery*;" and I made an extract from it in my work on *Diseases of the Heart*, the original publication being now very scarce.

Importance of employing the Ear with reference to the Prognosis.—The employment of the ear, in addition to the general symptoms, may be useful in this disease. It is always desirable, when a person spits

blood, to know how much disease exists in the lungs, and it is desirable to know whether the blood comes from the bronchial membrane, or is the consequence of such a state as this, because the latter form of hæmoptysis is far less manageable than the former. In this kind of hæmoptysis, called pulmonary apoplexy, when only a little effusion has taken place, you have a crepitous rattle, but in hæmoptysis from the air tubes you have not, and for this reason—because it is not in the air cells. When it is in the tubes it comes further off from the air cells, and therefore you have no crepitous rattle; for that always arises from an accumulation in the air cells of some kind or other. But in effusion in the air cells you have crepitous rattle at first, simply because it is in the air cells. In those cases, however, where the blood is more abundantly effused, you cannot have crepitous rattle, because no air can be admitted. The crepitous rattle I have no doubt arises from the air passing through the fluid, and the air bubbles bursting one after the other. When so much blood is effused into the different air cells that no air can be admitted into them, and the part becomes firm, there is no crepitous rattle, nor any rattle at all; no respiratory murmur, and no morbid respiration is heard, for no respiration can take place long in that part. All that you can detect by the ear is, that the part is not healthy. On striking over the part you find it sound dead, and on listening you find no sound of respiration, and you learn very well by the ear what is the extent of the mischief. In my case, the whole of the inferior lobe of one lung had undergone that change; had become quite solid. In those days the stethoscope was not invented; a work on this subject, which I shall have occasion to mention, was neglected, and I was taught never to use the ear, and therefore I knew nothing of the symptoms that would have presented themselves if I had employed that organ; but if I had employed the ear in this case, no respiration would have been heard over a great part of the chest, and on striking there would have been no hollow sound, and therefore I should have known the extent of the mischief. You may learn accurately the extent of the mischief in this disease; you may learn how much of the lung is solidified, by the extent of a dead instead of a hollow sound on percussion, and the extent to which there is no respiratory murmur. In regard to the treatment, that must be the same whether the blood come from one part or another, and therefore it must be for the sake of the prognosis that you employ the ear, and make a distinction between the two cases; the one being a manageable kind of af-

fection, and the other extremely unmanageable.

Treatment.—In hæmorrhage from the lungs, on the immediate occurrence of it, it is right to treat it as inflammation—to bleed in the arm freely, to set the patient upright, and keep him so, in order to make him feel as faint as possible. You should keep him in that position, instead of allowing him to lie down. It is safe to apply ice to the front of the chest, and this I think should always be done; there can be no impropriety in it. As soon as you have bled, until ice can be procured, you should throw cold water on the chest, and endeavour to produce a contraction of the end of the vessels, the same as you would in the case of the womb. But generally the bleeding soon stops; a patient seldom dies of hæmoptysis at the time. Bleeding at the arm, throwing open the windows and doors, and taking the clothes off the chest, answer very well. The patient should not be allowed to move; he should be easy and comfortable, but not allowed to move—not allowed to speak. I have often made persons persevere for a fortnight together after dangerous hæmorrhages, making them write for whatever was wanted. It is proper to starve the patient, to give him nothing but plain water, milk and water, lemonade, and things of that description, and it is surprising how patients in this disease bear cold. I know not a single instance of a person suffering inflammation of the chest from all this exposure, notwithstanding he would in all probability under other circumstances have suffered severely.

The best internal medicine by far is the superacetate of lead, and this must often be given in considerable quantities before it will stop the hæmorrhage. I myself within a month have had three cases of hæmoptysis, in which I have been obliged to give as much as three grains every four hours before I could fully stop it. It is always safe to begin with one or two grains every six hours, but if the hæmorrhage does not stop, but returns every day, it would be right to give such a quantity as this every four hours, and if that do not stop it, you may give three grains every three or four hours with perfect safety. In all these cases there has been as much as three grains taken every three or four hours, and no inconvenience felt except constipation, which was remedied every day by some laxative. If you do not attend to the state of the bowels, and procure a motion every day, the patient may become the subject of colic; but if you administer croton oil, or castor oil, or some purgative that has no sulphuric acid, there will seldom be any colic or pain of

the bowels, which is very troublesome. There is no occasion, so far as I have observed, to give opium. Some persons give opium, to prevent griping, but I have not done so, because I have not found a necessity for it.

Some persons give the lead in a liquid, and some in a solid form; but I have not exhibited it liquid, because it is very nauseous, and it answers just as well solid. It mixes up with the extract of colocynth into pills very well, and I have seen the stomach bear it much better if given in a pill, instead of the fluid form. That is the case with all acrid and nauseous things—the stomach can bear a pill the best. If the patient's stomach be disposed to reject it, it is useful to give one or two minims of hydrocyanic acid three or four times a day. If you be giving the lead only three times a day, then you might give hydrocyanic acid three or four times; but if you be giving the lead every four hours, then you cannot give the prussic acid so frequently. You will find the dose required to prevent the vomiting exceedingly various: in some, it will be prevented by one minim, three or four times a day, taken before the lead; and in other cases, two, three, or four minims, will be required. But of all medicines to prevent others from irritating the stomach, I know of none equal to hydrocyanic acid. Some apply blisters over the chest, and they are very useful in these cases at last, but the application of cold by means of ice is better. If the means be adopted which I have recommended, you will generally be able to control the affection. Treat it as an active inflammation in the first instance, and when the hæmorrhage is very considerable, treat it as a passive inflammation, or rather as active and passive; combine the two modes of treatment. Do all you can to prevent an excitement of the pulse, by bleeding from time to time, and keeping down the circulation, and at the same time adopt the treatment of passive inflammation, by producing a constriction of the vessels.

OBSERVATIONS

ON

GRENOUILLETTE, OR RANULA;

With an account of a New and Successful Mode of Treatment.

BY BARON DUPUYTREN.

From the "*Leçons Orales*," published periodically, under the Baron's inspection.

WE shall presently, said M. Dupuytren, as he was concluding one of his late clini-

cal lectures—presently we shall have to perform an operation on a young man, to excise two small tumors from beneath his tongue, near the point. What is the nature and origin of these tumors? Are they of that description known by the name of ranula or grenouillette? There may be some doubt of this. In the first place, it is rare for a ranula to make its appearance so near the point of the tongue; it generally comes beneath the base of its free extremity; and it is in consequence of this place of election that the diagnosis is often so difficult, and practitioners are sometimes liable to mistake, by confounding actual ranulae with tumors of a totally different nature. The mode in which tumors like those in our patient become developed, is this:—You are aware that the skin is provided with a considerable number of follicles, which secrete a certain quantity of oily matter. This secretion, which is scanty in the human species, is abundant in woolly animals, in birds, and especially in aquatic birds, in which it serves to maintain their beauty of plumage, and to protect them from the effects of humidity. In fishes it is still more abundant, and it lubricates the whole surface with a viscous and gluey liquid. In a similar manner the mucous membranes which line the internal surface of our organs are furnished; the follicles in those parts are incalculably numerous, and pour out an incessant supply of mucosity. Now these follicles, like every other tissue in the system, are liable to become diseased, and their secretion either suppressed altogether, or considerably modified in quantity and quality; sometimes it becomes excessively viscid, and again it is converted into an oily substance. Often too the little mouths of these follicles are closed up; the liquid which they contain accumulates; they are distended, become inflamed, and attain a considerable volume. These tumors are distinguished by their prominence, their transparency, their indolence, and, above all, by the gluey serosity with which they are covered. Seldom isolated, but generally multiplied and in groups, they are seen united together by means of this glue. They are met with most usually on the interior of the cheeks, on the front of the gums, or beneath the tongue. These tumors are in fact *mucous* cysts, developed at the expense of the follicles of that name, or they are *sero-mucous*, formed in the excretory ducts of the mouth. It is of importance to distinguish well these circumstances, until at least we are better acquainted with what we are to understand by a grenouillette.

As it is generally understood, the grenouillette, so called, either from the form

(that of a frog's back) which it assumes, or from the kind of intonation and utterance which its presence occasions, is a tumor resulting from the accumulation of saliva in the excretory ducts of the submaxillary glands, and sometimes of the sublingual glands; but the latter kind is said to be rare. The excretory ducts of the submaxillary and sublingual glands seem to be the only ones capable of this dilatation of their parietes, and retention of saliva. The duct of the parotid is formed of a tissue too dense and resisting to allow of the formation of such a tumor. Dilatation, in short, would seem to be exclusively the attribute of the former structures, fistula of the latter. There is, however, still much room for pathological anatomy to investigate, scalpel in hand, whether grenouillette really has its seat in the ducts of the glands just mentioned, or whether it consists simply in a cyst formed in a membrane analogous to serous tissue, and containing watery humour,—or, in fine, whether we must in every case recognize the same etiology as in the example of the patient who is about to be treated. It seems probable that tumors of various kinds, belonging indiscriminately to one or other of the three kinds, have been confounded, simply in consequence of their situation, under one and the same name by different authors, ancient and modern. Celsus, for example, looked upon the complaint as an abscess of a peculiar kind; and Ambrose Paré, in other respects so judicious and good an observer, fell into the same error. Actuarius pretends to have cured it by opening the vein, which induced Camper to infer, that he mistook the tumor for a dilatation of the vessel. Fabricius ab Aquapendente has placed grenouillette among encysted tumors, and has compared it to meliceris. John Munnicks believed that he had shewn it to depend upon an accumulation of saliva in the ducts which open into the canal, called after Wharton without any good reason, since Berenger of Carpi, who wrote in 1521, described it distinctly.

Some writers assert, that the grenouillette is a frequent complaint among infants, who carry it into the world with them; but do not these authors confound the grenouillette, correctly so called, with the serous sublingual cysts, which are sometimes very voluminous, and descend even to the sternum? M. Breschet, with that ability and erudition which is displayed in all his writings, has treated this subject in his *Repertoire d'Anatomie*: and it appears that he has five times opened these pretended ranulae, and recognised in them either simple serous cysts unconnected with the thyroid, or tumors of the like kind de-

veloped in the tissue of that gland. Camper observed in a very young female child two tumors of this description; he has also seen a ranula on either side of the tongue in several women, and in many men, but he states that he has never met with it in infants. The closure of the external orifice of the duct of the submaxillary gland may be the consequence of inflammation of the sublingual mucous membrane, or even of the substance of the tongue itself; apthæ and ulcerations about the aperture of the canal may also lead to its obliteration. In the division of the frænum of the tongue some of the excretory ducts sometimes are involved, and then obliteration may result from the cicatrization of the little wound. Calcareous concretions, or small calculi, found in these canals, may, by their development, oppose the flow of saliva, from which results an accumulation of that fluid, and a dilatation of the duct. It is rather difficult in practice to distinguish which of these circumstances has given rise to the disease, because it is easily produced, and the patients do not apply for our assistance till it has made considerable progress. Although most frequently the ranula only contains saliva more or less inspissated and changed, yet sometimes purulent matter has been found in the cyst, not unfrequently calcareous concretions. Instances are to be found in various periodical works, in which cases are related of such concretions being as large as an almond. J. L. Petit removed one which was as big as an olive, and Grentaud one equalling a pigeon's egg in size. Finally, Louis states, that Leclerc abstracted about a pound of calcareous matter, constituting a tumor of this kind, with which a man was affected.

In general, the symptoms of ranula are sufficiently perspicuous for an attentive observer to recognize. It is a soft, white, regularly-rounded, oblong tumor, situated under the tongue—fluctuating—without pain, redness, or other sign of inflammation—yielding a little under the finger, and speedily returning to its original form on the pressure being withdrawn. At first scarcely perceptible, then taking on by degrees increased growth, usually its volume does not exceed that of a nut, or of a pigeon's egg. As it augments, it pushes the tongue back—destroys the teeth—alters the voice—interrupts articulation—and interferes with mastication and deglutition. At last, the tumor finishes by becoming apparent externally, shewing itself under the jaw, and at the fore part of the neck.

The cause and nature of the disease being well known, it might appear easy to cure it; yet the history of our art shews, that this is attained but seldom, and with difficulty. Puncturing the tumor in the

mouth is the method most generally adopted; a bistoury, with a narrow blade, a lancet, or a trochar, are the instruments employed. If the fluid be limpid, and if there be no concretions, the contents of the cyst may thus be evacuated, and a temporary cure effected; but soon the aperture closes, and the saliva accumulates as before. Petit mentions a case in which the puncture was repeated ten times, but without getting rid of the disease. The incision may likewise be made under the chin, and the fluid evacuated externally; but this has generally been looked upon as injudicious practice, and apt to be followed by a salivary fistula, though the danger in this respect seems to have been overrated.

But the mere evacuation of the contents of the cyst is not the object which ought to be kept in view; we must also endeavour to prevent them from accumulating again, and, for this purpose, the opening must be kept from closing. This end is frequently attained by means of the actual cautery; nevertheless even this is not infallible. It is indeed remarkable, that an opening in a pouch distended by fluid constantly flowing from it should not prevent its closure; it is, however, an established fact, and one which would seem to prove, that, in the formation and maintenance of fistulæ, there is something more than the passage of a liquid, since a simple wound, or even one with loss of substance, is not sufficient to produce it in this instance.

Excision of a portion of the walls of the tumor, and extirpation of the whole, have been proposed, but cannot be recommended as feasible expedients. Again, it has been asked, whether an irritating injection could effect a cure by inflammation and adhesion? Even then, however, the functions of the gland would be rendered nugatory. Any thing like *catheterism* of the ducts, which has also been suggested, is difficult, and appears to me, besides, to be entirely useless.

[A verbose and very tedious enumeration of all the methods which have not succeeded is here introduced by the reporters, in order, as it would seem, to give more celat to the process recommended by M. Dupuytren; an account of the latter we subjoin.]

The method adopted at the Hotel Dieu, is to introduce a foreign body into the cyst after its evacuation, and thus prevent the puncture from healing—in the same manner as in fistula lacrymalis. To attain this end, M. Dupuytren caused to be constructed a little instrument, consisting of a hollow cylinder, through which the saliva escapes. The cylinder is four lines in length, and about two in breadth, and terminated at either end by a little oval plate, slightly concave on its free side, and convex on that

which is adherent to the cylinder. One of these plates is to be placed in the pouch, the other in the mouth. To give an idea of the contrivance, it may be compared to those little double-headed buttons which are united by an intermediate part, and which are still occasionally used for some parts of the dress. It may be made of silver, gold, or platinum; the last being perhaps the best, because it is least likely to be altered by the fluids of the mouth.

M. Dupuytren first employed it in a young soldier, affected with ranula. The following is the history of the case:—

CASE I.—Ranula of Three Years standing perfectly cured in Fifteen Days.

Duchateau, aged 24 years, ex-tambour of the Imperial Guards, of small stature and bilious temperament, had been affected for three years with a tumor under the tongue. It gradually increased without any pain, but greatly impeded the movements of the tongue. Anxious to get rid of it, he came to the Hotel Dieu, October 14th, 1817. On the side of the frænum of the tongue was seen a little oblong tumor, semiopaque, and occupying the site of the canal of Wharton, and apparently produced by the dilatation of the excretory duct of the submaxillary gland. Different methods had been adopted, but they had only removed the swelling for a very short time. The tumor had been incised by some, and its contents evacuated; others tried canterism; but still the disease speedily returned. M. Dupuytren proceeded as follows:—

An opening was made into the pouch with a pair of curved scissors, by which means a limpid, inodorons, viscid fluid was evacuated. The operator then took hold of the little instrument above described with a pair of dissecting forceps, and introduced it into the interior in such a manner that one of the plates was free in the mouth. From this moment the tumor became less; the incision healed on the cylinder; and in fifteen days Duchateau left the hospital perfectly cured. He could eat, speak, and perform all ordinary movements with the tongue without any restraint.

M. Dupuytren having perceived that the instrument was not quite perfect, had it slightly altered. The canal of the cylinder, for instance, was dispensed with as unnecessary.

CASE II.—Modification of the method employed in the last case.—Success of the improvement.

Vincent Tellier, aged 24, came to the Hotel Dieu, October 27th, 1820, having had, for many years, an oval tumor on

the left side of the frænum of the tongue. It was as large as a small hen's egg, and interfered with speaking, eating, and breathing. The operator laid hold of it with a pair of pincers, and cut out a portion with the curved scissors as before; the contents were evacuated, and the tumor became flaccid. One of the extremities of the instrument was introduced at the opening in the same manner as in the preceding case. The patient returned in eleven days; the saliva passed readily between the edges of the wound and the instrument. The latter had no effect either on the mastication or pronunciation, nor was the patient ever conscious of its presence. Some months after, when Tellier revisited M. Dupuytren for a dyspeptic complaint, the instrument was found undisturbed, nor had the tumor re-appeared.

Several subsequent instances of complete success, leave no room to doubt the perfect efficacy of M. Dupuytren's method. The following case is highly satisfactory, inasmuch as it affords a means of comparison of the two methods employed on one and the same individual, who had two tumors of the same kind, but independent of each other:—

CASE III.—Example of the Comparative Merits of the Old and New Methods of Treatment. Complete success of the latter.

Pic, a female aged 43, applied for advice at the Hotel Dieu, on the 5th July, 1824. She had a soft tumor, about the size of a small hen's egg, on each side the thread of the tongue. The voice was altered; respiration and deglutition difficult. By the touch it was ascertained that there was no connexion between the tumors. They had been growing for three months: how they originated could not be known. They had been opened three times, and a viscous transparent fluid was let out; but they as often grew again. M. Dupuytren, for the purpose of comparison, introduced his instrument into the right side, while he simply incised the corresponding tumor. The latter soon formed anew; and the Professor having treated it then as he did the other, had the satisfaction to see it perfectly cured. The patient has presented herself since at the hospital, and has had no recurrence of the disorder.

But in the treatment of this disorder, as well as in all others, we should not overlook the nature of the exciting cause; nor should we forget that the adroit practitioner must not be tied down to any exclusive method. We have already observed, that ranula may have its origin in inflammation of the excretory ducts of the sublingual and maxillary glands; and, when this is the case, the formation of the tumor

is prompt, and the tension, pain, and redness of the parts, leave us no room to mistake this kind with that arising from quite another cause. Here the retention of the saliva is only a consequence of the inflammatory state, and the cause being removed, so should the effect. Accordingly, we have here to combat the inflammation. Local bleedings ought to precede the surgical remedy. Grenouillette, in such circumstances, resembles retention of urine occasioned by inflammation of the bladder, or the annexed tissues—where the evacuation of the liquid is but a means, and general and local antiphlogistics can be by no means dispensed with.

This complaint may, moreover, as we have said, be *simulated* by tumors developed in the same place, or its immediate neighbourhood. Inflammation, in fact, of the sublingual and submaxillary tissues may give rise to appearances—such as abscesses, or serous cysts—which bear a strong resemblance to the tumors of grenouillette. The following case will shew how the diagnosis may be made :—

CASE IV. — *Sublingual Lipoma simulating Grenouillette.—Extirpation.*

A female, 69 years of age, a sempstress, was taken into the Hotel Dieu. For four months she had been labouring under the following complaint. An indolent tumor was developed beneath and rather to the left of the end of the tongue. It gradually displaced that organ by its growth; and at last, after extending to the base of the mouth, it formed a projection at the upper and left lateral portion of the neck. Several practitioners, who were consulted, pronounced it to be a grenouillette. When the woman entered the hospital the tumor of the tongue was about the size of a pigeon's egg, soft, and evidently fluctuating. At that part of the neck just mentioned, there was a connected tumor about the size of a moderate apple, and this, too, had a semblance of fluctuation. A great irritability, physical and moral, marked the general condition of the patient. There might seem to be room to doubt whether this was lipoma or grenouillette; but M. Dupuytren soon ascertained this point, by introducing a straight bistoury into the tumor beneath the tongue. No liquid came forth; but from the fatty tissue which presently made its appearance between the lips of the wound, the lipomatous nature of the tumor was made evident. Extirpation was effected, as the nature of the case required.

There were other points in the foregoing instance which might have led to a correct diagnosis even without puncture. The volume of the tumor, within the mouth, was

less than it usually is in old ranulæ which extend to the upper part of the neck; and that narrowing of the volume, between the tongue and neck portions, was also unusual in grenouillette. When the latter extends so far it continues its rotund form throughout, and this would mark pretty clearly the difference in the preceding case. But the *puncture* is certainly the most satisfactory method of exploration.

REMARKS

ON THE

INFLUENCE OF PHYSICAL HABITS AND EMPLOYMENT

ON THE

SIZE OF DIFFERENT CLASSES OF MEN.

By J. BLACK, M.D.

Of the Royal College of Physicians, London.

IT is well known to the student of the natural history of our race, how much the different tribes of mankind are modified by climate, and how their physical growth and conformation are improved or deteriorated by civilization, diet, and employment. It has also been long remarked, that similar races and families have undergone corresponding modifications from change of climate, food, and occupation. Confining, however, the subject of this paper to the resident inhabitants of this country, and throwing out of our consideration the agency of climate, to which may be added even that of diet, as affecting the results of the question in any way beyond that of constituting a general influence applicable to all—we shall offer a few observations on the more restricted effects resulting from physical training and employment alone.

The physical education of children has been much commented on and talked about of late years, yet, in practice, it is still greatly misunderstood and neglected. The prevailing ambition of the rich to force "the young idea" to shoot forth its precocious fruits in their children, and the wants and temptations of the working classes to convert the little hands of their offspring to some pecuniary utility, have equally tended to frustrate the acknowledged maxims of this important department of education. Wealth, the slave of

fashion, and poverty, the victim of necessity, are, in some degree, subject to the same retributive afflictions. The offspring of the one early become phthisical, nervous, dyspeptic, and laterally curved in their spines; while a corresponding portion of the other become the melancholy objects of rickets, mesenteric disease, scrofula, anteriorly bent spines, and twisted limbs.

Without adverting to the whole agencies slowly but effectually acting on the growth and symmetry of the child, the simple articles of jacket, stays, boots, and shoes, have a gradual but marked influence. The first in confining, with the aid of the waistcoat buttoned up to the throat, and the broad leather or cloth belt, as lately worn, the due expansion of the boy's thorax, and, above all, excluding the access of the vivifying atmosphere from the surface of the body,—an habitual admission of the air to which, it is of so much consequence to encourage.

The stays of young girls, again, have not only the same pernicious effect, but also that of preventing the growth and formative contour of the ribs and muscles of the chest and spine, so essential to the requisite strength of the vertebral column and the proper freedom of the thoracic and digestive organs. The laced boot, in either sex, has also the injurious effect of anticipating the supply of effective muscles for moving the foot, by which the calf is kept down and the heel is disposed to elongate. The strength of the muscles and tendons, with the aid of the laced boot, at six years of age, will be sufficient for the child at ten, without any addition to the mass of the moving fibres of the limb. The want of proper clothing among the children of the poor, and especially those who are subjected to daily work within doors, has, more directly, similar injurious results, from the greater exposure of the surfaces of their bodies to the different states of the weather while under more or less previous warmth and perspiration. The wooden clogs which are worn in many of the manufacturing districts, have nearly the same unfavourable effects on the muscular development of their legs and the form of their foot, however preventive of colds, &c. as the laced boot has. The sole of the clog, or sabot, being thick and inelastic, the foot has no spring nor play

in its movements, being only lifted up and set down in walking. The nature of the motion is such, that the muscles of the thigh and pelvis are more particularly called into action, while the gastrocnemii, with their tendons, are little exercised; the whole tending to flatten the foot, elongate the heel, and repress the elastic symmetry of the leg. These effects are readily observed in the youth of both sexes belonging to factories, or employed in weaving, and in the otherwise stout and healthy lads that are brought up as colliers, carters, and as farm servants. The favourable contrast is seen in those children who wear only the lightest shoes, and even in those who wear no shoes at all; the former of whom will only have more compact and shapely feet, while the latter will have them broader, but with calves and heels in equal perfection. The feet and legs of the Irish peasant, and of the Scotch and Welsh mountaineer, contrasted with those of the better fed English labourer, will illustrate the observation.

How different, also, the feet of the thorough-bred seaman from those of the farm servant, and even of the soldier, who has been enlisted with no defect in his limbs! The foot of the seaman is comparatively small, well turned and knit, from wearing the small slipper-shoe, and from the frequent and powerful exercise to which the posterior muscles of his legs are subject in climbing, &c.; while that of the English ploughman is generally long, flat, and has a projecting heel, with little calf. This latter conformation is more particularly observed in the aged labourer, owing to the long use of the thick sole and tight lacing of his working boots. The legs of the foot-soldier are more fully provided with muscles, and have more contour than those of the dragoon, owing to the different calls made on the exercise of their lower limbs. The dragoon, however, sooner acquires, and longer preserves, a better *embonpoint* and more abdominal girth than his fellow of a marching regiment, the play of whose abdominal muscles, in walking with his arms and accoutrements, keeps down his abdomen, while the bulk of his limbs are relatively increased. Coachmen also exhibit a marked difference in this respect from the waggoner, navigator, or waterman; all of whom are equally well

dieted and exposed to the healthy influence of the air. Jehu often sits on his box, the type of a ruddy Hercules, with his slender limbs encased in top-boots; while the others wield their whip, or the oar, with brawny shoulders, slender waist, and with more muscular and sinewy, though often uncouthly-formed, limbs. All curious observers have remarked, in general, the quick and upright gait of tailors, with their slight inclination of the right shoulder forwards; the broad shoulders and muscular arms of the butcher and baker, however different their complexions usually are; and the spare figure, the lank and bent limbs, of the hand-loom weaver, and the parallel motion of his feet in walking.

In different classes of operative men, tall as well as short individuals very frequently appear, however unfavourable the occupation may be for developing the muscular mass of the body; and it appears that the habits and occupations of life influence the girth of the body, or the muscular growth, much more than the stature. This last seems to be affected more by hereditary impression and congenerous descent than the circumference of the body or the breadth of the chest is. Indeed, in many cases, great stature is accompanied with relative muscular weakness, and is not seldom the effect of debilitating causes long acting on the body during growth, but without injuring the functions of accretion. In the convalescence from fever in young people, we often find the body take on a remarkably quick increase of stature; which may be partly owing to long recumbency, which allows the vertebral column to elongate without consolidation from exercise.

Observations on these general effects, induced me to ascertain exactly the comparative difference between two bodies of men, brought up from their childhood and employed in very different occupations, but residing in the same neighbourhood—both acquiring nearly the same rate of comfortable wages, living on the same diet, and generally all natives of the same district. The two classes are, the operative cotton-spinners and the crofters, or operative bleachers of cotton goods, by the aid of machinery, water, and chemical detergents: and, in order to complete the interest of the investigation, I have

compared, by actual measurement, their respective statures, girths of body, and their averages with those of the same number of soldiers, who, being long in the army, have been subjected to many and different physical circumstances acting upon their bodily growth and figure.

Before referring to the tabular exposition of these results, as set forth hereafter, I shall state, for the information of those who may not be well acquainted with the nature of the employments of the operatives under review, the direct and collateral influences to which they are respectively and habitually subjected.

The class of spinners that were examined, have all been brought up, with only one or two exceptions, from their childhood in the cotton factories; entering at first as piecers, from 7 to 12 years of age, and going through other subordinate offices in the card room, &c. till they acquire the charge of the spinners' wheels, which, if they are active and steady, they generally do at the ages of 19 to 21, according as they are wanted. All those whom I examined had been in the factories from seven years at least, with the above exceptions. During this period of juvenile labour, they work the full time of the adults, varying in different mills from twelve to fourteen hours daily, excluding time for meals; and they are exposed to an atmosphere more or less dusty, with a temperature varying from 75 to 90 degrees, according to the fineness of the yarn that is manufactured. Their diet may be said to be sufficiently plentiful and nourishing, as the generality are children of the operatives themselves, who have always enjoyed good wages. The children of weavers and of widows, are, of course, not so well clothed or fed, from the necessities of their parents. The young men, when put to a wheel, have wages varying from 24s. to 30s. per week, and, whether married or not, have good cottages, and much in their power, as to domestic comfort, if they and their wives were to make the most of their means and situation.

I shall not enter into any notice of the constitutional diseases and moral habits of this class of work-people, as these subjects have been well treated of by a few medical statistical writers of late.

This is, then, a condition of life, exclusive of hereditary descent in most instances from families similarly engaged, which offers a definite field for ascertaining the effects of habitual occupation on the physical development. Accordingly, I measured 50 spinners from one mill and 50 from another, both in the town of Bolton; and to obviate all errors in the average, I took them as they stood on their lists, from 19 years of age upwards. Of these 100, six were 19 years of age, seventy were from 20 to 29 inclusive, seventeen from 30 to 39, and seven were from 40 to 45: the last being almost the utmost age at which any spinners are found at work.

The crofters, or working bleachers, are generally the sons of those similarly employed, or of labourers, weavers, or farm servants. They commence their services in the croft or bleach-work from 12 to 17 years of age, and are exposed to a good deal of varied muscular exertion, in carrying and turning over pieces of cloth from one washing-wheel, vat, boiler, or steaming-vessel, to another; subject at all times to be wet, from water at the natural temperature of the season to that of a boiling heat, and generally to an atmosphere charged with aqueous vapor. Lime and alkali, in hot solutions, are often the menstrua of their work; and, from the extensive use of the chlorides in bleaching, they often breathe an atmosphere more or less impregnated with the chlorine gas: besides that, in many of the bleaching establishments the chloride of lime is prepared on the spot. The habitual manipulation among water and steam keeps the surfaces of their bodies very clean; and though the changes from cold to warmth and even heat, from dry to moist, are daily and constant, in going through their work and to and fro to their homes for their meals and rest, they are a very healthy body of men. They are seldom subject to dyspeptic, intestinal, or pulmonary diseases, except to a smart pneumonia on rare occasions; and the most frequent complaint to which they are liable is rheumatism. They are a fine body of workmen, and there is every reason to attribute their good health and muscular development, to the cleanliness of their persons, and the sort of case-hardening their constitutions experience in the al-

ternations of temperature and moisture, somewhat similar to the bracing effects of the Russian baths, as well as to the frequent inhalations of diluted chlorine. Their wages vary from twenty-four to thirty-four shillings per week, and their cottages are exceedingly comfortable in many of the establishments. Their dress is adapted to their feelings and employment; and a stranger passing through this neighbourhood, has, no doubt, at times inquired what class of people are they who are clothed in short, white, thick woollen jackets, with their waistcoat and shirt-collar thrown open, and exhibiting a neck and breast of hardy proportions and as ruddy as the cheeks of a mountaineer?

From the number of this class employed in this place and neighbourhood, amounting to some few thousands, I selected two principal works and took the measurement of 50 from each, as stated in the table, and as they stood on the books of the respective concerns. Of these 100, two were 19 years of age, forty-five were from 20 to 29 inclusive, thirty-three from 30 to 39, thirteen from 40 to 49, and seven from 50 to 63.

The training, diet, exercise, and habits of soldiers are well known to all. I shall only observe, that the 100 men of the 85th regiment gave me a good opportunity of a comparative inference, as the corps is a light infantry regiment, having no picked flank companies, and the men being a long time in the army. The two companies were measured, through the kind liberty granted by the commanding officer, as they underwent inspection; and of these, one was 19 years of age, thirty-two were from 20 to 29 inclusive, fifty-one from 30 to 39, and sixteen from 40 to 49. Forty-six had been in the army above 10 years, fifteen had been above 20 years, and one was 34 years in the service.

The height, in all these cases, was taken without shoes or stockings; and the circumference of the naked chest on a line close below the nipple. The heights are marked at the progressive proportions of an inch, which includes all the fractional ones between that and the next lower inch; and the inches of girth denote all at any one round number, and the fractional ones from the foregoing number.

Comparative Averages of the Ages, Heights, and Widths round the Chest, of the above-stated three Classes of Men.

CLASS.	Age in Years.	Height.		Width.
		<i>Feet.</i>	<i>Inches.</i>	<i>Inches.</i>
100 Cotton Spinners	26.71	5	4.64	32.67
100 Crofters, or Bleachers	32.12	5	6.75	34.24
100 Men of the 85th Regiment	32.67	5	7.87	34.8

From the above tables some interesting inferences may be deduced; and, if they had embraced a larger number of the same or other classes of workmen, they would lead to some very important statistical and physiological information. From the fair manner in which the measurements were taken, I am, however, confident that a more extended investigation of the same classes would be followed by the same average results; and it certainly will become, in the course of a few generations, a subject of more interest to ascertain whether the succeeding families of such operatives (for the females are undergoing nearly the same physical influences from work, diet, and confinement, as the males) will present an increasing disparity in size, according to the length of hereditary labour and employment. Notwithstanding the comparatively stunted growth of the spinners, it is satisfactory to find that they do not labour proportionably under disease, as I have ascertained from the returns of their sick clubs; but as this is a subject on which I do not choose to enter at present, I shall conclude by presuming that the above observations and tables may be of some interest to the readers of your respected journal.

J. B.

Bolton, April 16, 1833.

BANDAGE IN PARTURITION.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following observations on the use of the bandage in parturition, which were lately read before the York Medical Society, be deemed worthy of a place in your valuable journal, I shall be much obliged by their insertion.

In consulting the most approved writers on midwifery, I have been surprised to find no allusion to the use of the bandage during parturition, except in Ingleby on Uterine Hæmorrhage. Many have strongly advocated its application *after* delivery, as a means of arresting hæmorrhage, by exciting contraction of the uterus; yet, even for this practice, I am not aware that any have recommended its application previous to the birth of the child or secundines, though, on reflection, it must be evident that to render it effectual as a preventative, it should be used before the uterus is evacuated, to excite due contraction and prevent relaxation.

As to the kind of bandage, and method of applying it, I need only observe, that, after a variety of trials, I have found the common cotton shawl to answer all purposes, and form one of the best; this is folded up corner ways, so as to make a belt about fourteen inches broad, or so wide as to completely encircle the abdomen, and then crossed or tied at the back. This kind of shawl, from its size and soft elastic nature, forms a comfortable and easy bandage, readily yielding to the motion of the patient, and is far preferable to the napkin or towel, which do not so readily become adapted to the figure, besides lacking that elasticity so essential to comfort. Care should be taken that it is neither too thick to prevent easy adaptation when the body becomes smaller, nor too thin in substance, so as by slipping together to form a mere ligature; thus failing in its main object, and giving pain rather than support during delivery.

With regard to the period of application, I cannot go so far as Ingleby, and say, that it is most useful when applied on the accession of labour, and therefore always to be used in the first stages; but I deem it most suitable

when the os uteri is tolerably dilated, and connected with that state of the soft parts which requires but a little uterine force to overcome the resistance, and then the bandage will give effect to this power; but to use it previous to this condition, would be to excite such action as might probably exhaust the patient ere the last stage had come on; in first cases too, it might be attended with other bad consequences, as too early rupture of the membranes, thus endangering the safety of the child. If the pains were unusually rapid and strong in a first case, I should be cautious in using the bandage, except during the expulsion of the child and secundines; yet in certain difficult first cases I have seen it supersede the use of the forceps.

The different ways in which I conceive the bandage may be made available to the accoucheur, and advantageous to the patient, are the following:—

1st, When firmly and steadily held, it fixes the trunk, and enables the patient to direct her energies to the uterine power.

It may be said that parturition is a natural process, and ought not to be interfered with; this, with some limitation, I grant; and where woman is in a state of nature, what I here recommend would be almost always useless. But in civilized society the case is far otherwise.

2dly, The bandage I imagine to be also the most powerful and universal stimulant to uterine action that we have; for by firmly grasping the abdomen, it presses particularly on the fundus uteri, as well as partly communicating a lateral pressure. The stimulus that friction produces is trifling, and can seldom be long continued; the pressure of the hand on the fundus uteri is objectionable, from the great pain it induces, if at all efficient, besides the difficulty of keeping it steady. The bandage, by regular and equal pressure, excites the uterus without additional pain, and can be regulated at the accoucheur's will, according to existing circumstances.

3dly, The bandage gives efficiency to uterine efforts by mechanical assistance, if not also by increasing muscular power. That it mechanically aids labour, I think, is easily comprehended, when you consider that at the time the uterus is powerfully contracted, it forms almost an unyielding resistance; hence

pressure on its fundus and sides must mechanically force its contents downwards, in the direction given by the longitudinal fibres of that viscus, and thus aid the efforts of nature, which in some cases I have found so unequivocally proved, that its descent would be more advanced by pressure than the pains.

4thly, The bandage, by pressure on the fundus uteri during the expulsion of the child, causes its proper contraction on the placenta, preventing the justly-dreaded consequences of relaxation of that viscus. The only caution here necessary is, that after the head has passed the os externum, and while the shawl is drawn tight, care must be taken that the child is not too rapidly expelled; care should be taken rather to retard the egress of the body and extremities. By mere mechanical pressure, and the consequent stimulus it possesses, you command the proper and natural contraction of the uterus, escaping the greatest evil the practitioner has to contend with; for "more women die of hæmorrhages succeeding labour, than from all the other fatal causes of parturition taken together."

5thly, and lastly, The bandage is advantageous in preserving the relative position of the viscera, after the evacuation of the uterus; for it effectually prevents that syncope which is often so distressing to the patient, and not unfrequently the first cause of uterine relaxation, and consequent flooding.

Thus have I briefly attempted to describe the advantages of this application; and in conclusion shall merely add, that where the assistance here recommended has been resorted to, the patients have expressed their surprise at the great relief which they obtained, and have attempted to account for it by supposing that it possessed some more mystical virtue than the mere girding of a shawl.

I must apologise, sir, for the space which I have filled*; but anxious to direct the attention of others to a subject of so much importance, I trust you will excuse

Your obedient servant,
JAMES ALLEN,
Surgeon.

York, March 27, 1833.

* We have taken the liberty of abridging this paper very considerably; but we trust without leaving out any thing essential.—E. G.

MEDICAL JURISPRUDENCE.

POWERS OF CORONERS—PRIVILEGES OF MEDICAL MEN.

To the Editor of the Medical Gazette.

SIR,

THE general practitioners of Wakefield have formed themselves into a society for the mutual communication of knowledge and the support of the interests of the medical profession.

Among the matters lately discussed, the subject of coroners' inquests was introduced, and the following resolutions were passed.

As secretary to the society, I beg to present them to you for insertion. If they obtain your approbation, I need scarcely add that we shall feel most happy to have the support of your powerful pen.

I am, sir
Yours obediently,
BENJAMIN WALKER,
Surgeon.

Wakefield, April 27, 1833.

At a meeting of the Wakefield Medical Conversazione,

Resolved,

1st. That the medical profession is a learned, moral, and reputable one, and it is therefore requisite that the practice of medicine be adequately remunerated.

2dly. That the office of coroner is one of high and important trust; and that the institution of "inquest" is one of the most important parts of the British constitution, and can seldom be well conducted without medical evidence and opinion; and therefore it is highly necessary that the study of jurisprudence be well understood by medical men.

3dly. That, in order to induce medical men to bestow time and expense on this study, it is requisite that jurisprudential knowledge and ability should be adequately rewarded.

4thly. That the non-existence or uncertainty of the law on the subject of medical remuneration for attendance on the coroner's inquest, is a great hindrance to the prosecution of forensic studies in medical men.

5thly. That it is expedient that this be brought before parliament as early as possible, in order that such an injurious grievance may be removed.

6thly. That it is unreasonable and un-

just for medical men to be compelled by the writ of the coroner to attend an inquest, and give not only evidence but also scientific opinions, and to be unable to claim remuneration for what they do, or compensation for what they lose.

7thly. That it is inexpedient for so large and important a profession as the medical one is, to remain unrepresented in parliament, and that it is the imperative duty of the medical profession, therefore, to obtain for their interests a voice in the legislature of the kingdom.

8thly. That these resolutions be forwarded to the Medical Gazette and the Lancet, and that the profession generally be requested to take an active part in obtaining that just and equitable attention to its interests which is due to it.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

The Anatomy and Physiology of the Organ of Hearing; with Remarks on Congenital Deafness, the Diseases of the Ear, some Imperfections of the Organ of Speech, and the proper Treatment of these several Affections. By DAVID TOD, M.R.C.S.

THE peculiarly comfortless condition of persons who want the power of hearing has been frequently remarked; and shrewd observers have doubted whether the loss of any other sense could be productive of more unhappiness. With the exception of the touch (and with this, we fancy, it is not quite fair to institute a comparison, extensive as it is, and never wholly absent while life is present), there are, perhaps, none of our senses so precious. Milton eloquently deplores his being "in darkness, and with dangers compassed round;" but would he have been in a less deplorable condition compassed round with danger in deafness? What misery would he not have felt had he been cut off from that "sweet converse" which he could so exquisitely appreciate! But ordinary mortals, as well as poets, can feel sensibly the misfortune of being deprived of the sense of hearing; and this quacks know. There are few organs of the body which have so exclusively en-

gaged the attention of empirical practitioners as the ear; there is just enough of difficulty and mystery about the structure and functions of the organ to enable them to mystify *ad libitum*, and to render it a rich field for their exertions. Some of them have written books, and such books—as make it imperative on persons properly qualified to take the subject out of their hands. The volume before us is likely to do good service in this respect; it is among the few that we have met with, in which the actual knowledge that we possess regarding the ear is clearly stated, and that knowledge rendered available by being chiefly conveyed with a view to practice.

In the anatomical part Mr. Tod is very minute and satisfactory. He has given several plates descriptive of the structure of the ear, and takes credit to himself for having made out several parts about the organ, not as yet noticed by any other anatomist, but which he says he can demonstrate from preparations in his possession. The physiological portion of the work is equally full, and of course still more interesting. But what particularly fixed our attention, in the perusal of the volume before us, was the account which it contains of congenital deafness—a subject which would deserve to be considered the test or touchstone of the practical aurist. How far is he enabled to assist nature in removing impediments which have existed from birth? Mr Tod has given us a few cases of his method of proceeding in such circumstances; we shall extract one or two of them, as serving to exemplify the practical doctrines which he lays down on this difficult and almost hopeless subject:—

“ Sarah Fulford, ætat. 10, of No. 8, Great Swan-alley, Coleman-street, a girl of a good but delicate constitution, and apparently free from all hereditary complaints. At birth she was observed to cry very indistinctly, and afterwards, when asleep, no noise could awake her. Little attention was paid to these circumstances until she was nearly two years old, when she was discovered to be deaf and dumb, and in that state she has continued ever since. To-day, March 10, 1828, she was placed under my care. I learnt that she could hear the sound of a bell when rung close to her, and that with great difficulty she could articulate several words, such as

father, mother, beer, &c., which she had learnt from the motions of the lips of others.

“ On examining the meatus of each ear, there appeared to be a plentiful secretion of wax, and the membrana tympani seemed to be entire, but apparently more concave than usual. On introducing the soft bougie, however, I found that although the membrane appeared perfect to the eye, it was very much malformed; that the handle of the malleus was external to it, and attached to the incus instead of the malleus. The right ear was still more malformed, and more insensible to sound than the left. Considering the case to be capable of relief, I explained to the parents the importance of her living in a pure air, and having her digestive organs strictly attended to.

Ordered a perpetual blister to the nape of the neck, and a mild aperient pill to be taken every night.

March 17th.—Hearing and speech a little improved. Syringed both ears with tepid water, and plugged them with lint moistened in linimentum camphoræ.

Ordered the former remedies to be continued.

24th.—Hearing and speech continuing to improve; and she now notices and articulates the simpler sounds with facility. Was told that, since she began to improve, she has evinced a great desire to learn to read, and that she can now repeat many of the letters of the alphabet.

Ordered all the remedies to be continued.

31st.—Speech greatly improved; can now ask for various articles, and execute errands with some facility. Hearing also improved, but apparently not so much as the speech. General health considerably better.

Ordered all the remedies to be continued.

April 14th.—Hearing and speech continuing to improve; can now hear what is said, but is unable to make a reply,—evidently shewing the speech to be in its infancy. Was told that she pays more attention to the conversation of children than adults. Applied a few drops of æther rectificatus to each tympanum, which excited much pain.

Ordered all the former remedies to be continued.

20th.—Hearing and speech progressively improving; and I was told to-day that she had heard the music of an organ in the street, apparently for the first time, which delighted her much. Syringed each ear, and brought away a quantity of adventitious membrane.

Ordered all the remedies to be continued.

27th.—Hearing and speech considerably improved; can hear better with the right ear than the left. Removed from the former, by the syringe, a quantity of membrane.

Ordered all the remedies to be continued.

May 11th.—Hearing and speech improving. Omitted the æther, and applied a little tinct. cantharidis instead.

Ordered all the other remedies to be continued.

18th.—Continuing to improve.

Ordered the blister to be healed.

22d.—Continuing to improve.

At every visit after this period she displayed a progressive improvement in her hearing, speech, and general health; and in a short time she appeared to require nothing more than a teacher."

In the following case there seems to have been much more to contend with than congenital disorder or malformation: the ravages of quackery evidently made the case desperate:—

"Señor Antonio E., a native of Barcelona, ætat. 18, deaf and dumb from birth. When about nine years old he was put under the different medical practitioners of his native place, in the hope of obtaining his hearing; but after three years' attendance, his case was by all pronounced hopeless. On examining the tympanum of each ear, I perceived that there had been originally no malformation, but that the membrane or drum was now entirely destroyed. This defect appeared to have been produced by the different kinds of treatment which his medical attendants had pursued. He is now (Christmas 1828) more deaf than any one I have ever seen; for he can scarcely hear any sound, even although the sonorous body be placed in contact with the skin covering the mastoid process. There appears, however, to exist a sensibility sufficient to allow the conclusion, that the textures of the labyrinth are entire. Syringed both ears

with tepid water, and applied to each a small quantity of linim. camphoræ cum liq. volat. cornu cervi, and plugged them with lint.

Ordered the liniment to be repeated every night, and to take an aperient pill occasionally, to solicit the secretions.

Jan. 22d, 1829.—No improvement. Observed the meatus of each ear to be inflamed; poured into each a little æther rectif., and plugged them with lint. Signified that the æther had gone into his throat, and that he felt great pain.

Feb. 3d.—No improvement. Applied to each tympanum a few drops of liq. ammon. fort., which caused severe pain.

Ordered the Linim. Camph. cum Liq. Volat. c. c. to be repeated every night.

18th.—No improvement. Repeated the former applications.

Shortly after this period he determined to discontinue the treatment; but in about three months afterwards, one of his family called, and stated that his hearing was apparently a little changed, for that he had applied a hearing-trumpet to his ears, and signified that he could hear sounds which he never could before. The case, however, appearing to me hopeless, I did not give any encouragement to renew the treatment."

The plan judiciously adopted by the author in such cases, is to imitate nature in the cures which she sometimes spontaneously effects. In a case (Phil. Trans. vol. xxiv.) an individual in the seventeenth year of his age obtained his hearing and speech when recovering from a fever; and Buffon relates a case in which a person of 24 years of age obtained his hearing and speech, from the left ear having accidentally become the seat of inflammation which terminated in suppuration. "As long as we endeavour," says Mr. Tod, "to solicit actions of the same nature as in these cases, we cannot do injury, and may possibly effect much good. When our efforts to afford relief succeed, it demonstrates the correctness of our views of the nature of the case, and our knowledge of the animal economy; and when they fail, it proves that our notions were either hypothetical, as they regard the disposition of the organ and the choice and use of the remedies, or that the defect was beyond their reach;

but by no means that it was impossible to alleviate or remove them."

There are several interesting eases related by the author, illustrative of his treatment of diseases of the ear; and the volume concludes with a short chapter on the disorders of the organ of speech. We have only to add, that the principles laid down under this head are marked by the same judicious regard to the peculiarities of the natural processes, as we have already noticed. The book is practical throughout.

Outlines of Human Physiology. By HERBERT MAYO, F.R.S. &c. &c. Third edition, 1833.

MR. MAYO'S is beyond all question the best manual of physiology in the English language. In the present edition we observe numerous instances in which fresh matter has been introduced, so as to bring the whole down to the most recent date. We may mention in illustration the sections on the "mechanism of speech," and on "the development of the embryo," the former of which contains some original observations made on a case at Middlesex Hospital, and first published by the author in this journal; the latter an excellent digest of what is known on the subject, taken chiefly from the German writers. In the section which relates to the connexion of the embryo with the uterus, Mr. Mayo does not enter into any minute details regarding those controverted points which we so fully discussed a fortnight ago. The chapters on the brain and spinal cord are elaborate and interesting; and we are glad to observe that the author does justice to the labours of the industrious and scientific Reil, as contrasted with the "shewy anatomy" and "bold conjecture" of Gall and Spurzheim. The work is illustrated by numerous engravings, introduced along with the text, by which the eye is addressed at the same moment as the understanding, and the comprehension of what might otherwise be obscure is greatly facilitated. The student of physiology will no where find so much original matter, combined with so much taken from the labours of the continental writers.

MEDICAL GAZETTE.

Saturday, May 4, 1833.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri: potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

WORKING OF THE CONCOURS SYSTEM.

FOUR or five weeks ago we noticed the opening of the Concours at Paris for a professorship of *Clinique interne*: we mentioned the extraordinary length of time that the chair was allowed to remain vacant, the tediousness and reluctance which those who had the management of the Concours manifested in getting it up, and the discontent, and the anticipations of foul play, so loudly expressed by all who took an interest in the matter in the French metropolis. Well, the reader will say, it is surely all over now; how was it decided?—you cannot mean to insinuate that the thing is still *sub judice*? Yes, but we do, though. The Concours, be it known to you, gentle reader, is as yet scarce begun; the machinery has just been tried for one *épreuve*, but has worked so vilely, and with such serious symptoms of an explosion, that all people are out of conceit with it, and will scarcely trust to it any longer.

This first test or trial was a professedly deliberate and impartial examination of the anterior merits of the candidates. It was proposed to ascertain, and to take into account, the services which those gentlemen had already rendered to science, and particularly what works they had written and given to the world. The design of this arrangement was good. It is clear that if the Concours were to be confined merely to oral and written proofs, in many instances the junior candidates would have a great advantage over their elder competitors, inasmuch as, coming

fresh from the schools, they would be familiar with the several branches constituting the *science* of medicine, and by the aid of memory alone, combined with a faculty of extempore speaking, would perhaps leave behind them in the race men their superiors in practical knowledge and skill. The proposal was therefore a wise one, to appeal to the past, and gather from it a prudent judgment as to future expectations.

But in adopting this procedure in the present instance, the jury unfortunately did not escape suspicion. It was broadly hinted that they had their favourite candidate, whose known preponderance in the way of *titres antérieurs*, would easily enable them to set him at the head of the list; and although the result does not seem to have justified the suspicion, (the person who has actually obtained the highest place being not the man who was supposed to be the favourite,) yet the discontent is not the less. People who predict unpleasant consequences are seldom more annoyed than when their predictions turn out untrue.

Another charge is brought against the jury; it is averred that their mode of estimating the anterior merits was improper, and open to dangerous abuses. They examined the claims of the candidates in this respect with closed doors, and they expressed the order of what they conceived to be the respective merits by numerical ciphers: this, it is asserted, was highly objectionable. There is much room to suspect wilful mystery in the adoption of ciphers for such a purpose: the members of the jury, according to an arrangement among themselves, took each a particular candidate's *titres* into consideration, and allotted ciphers just as they thought fit. What regulation, if any, may have been previously made by the tribunal, regarding the scale according to which each cipher was allotted, is not known,—

but the mode of proceeding is condemned as having been altogether too arbitrary. Provision should have been made—and people are not satisfied that in this instance any such has been made—to regulate the numerical adjudication with a twofold reference; first, to the actual value of the *titres antérieurs*, compared with the other proofs of merit to be subsequently given,—and then to the relative value of each candidate's merits, compared with those of his competitors. Whether this was really done by the jury, we are not prepared to say; we only know that, what with the unexpected result—the supposed possibility of exercising undue favour, especially as this proof has been taken in a private manner—and what with the jealousy which has been entertained of this jury from the commencement, a great outcry has been raised against the first act of the present Concours.

Reluctance and indecision marked the early proceedings of the jury: a mongrel and incongruous body in their formation, partly consisting of the professors of the school, partly of delegates from the academy, and all under the appointment and surveillance of the government, they were looked upon with no confidence from the first; they then showed themselves but too anxious to desert the duty which was imposed upon them, framing various excuses, and several pleading illness in apology for being absent; they contrived various delays; and, on the whole, the policy of conduct which they have hitherto pursued, has been construed in any thing but a favourable sense by the friends of the Concours. Some of the latter can hardly persuade themselves that it is not all a dishonest trick, and that the jury have not a studied determination of turning their admired mode of appointment into downright discredit and ridicule.

But the candidates—how do they

take the treatment of their judges? We mentioned, in our former notice of this subject, that all of them except two had protested in the first instance against their court of examiners, and that their protest went for nothing. Since then many complaints have been made of the delay—the repeated adjournments of the court pressing as a serious grievance on some of the candidates, some of them being taken away, for a time infinitely longer than they had calculated upon, from their practice, and all kept in an intolerable state of doubt and suspense. This, however, is nothing to what has happened on the announcement of the result of the *première épreuve*. All the candidates save one (M. Rostan) who has obtained the highest cipher, are in high dudgeon; all, save the same gentleman, have protested against the decision of the jury, and the greater number of the party have retired. Add to this, that further delay has been occasioned by some of the jury being obliged to set out for Blaye on a politico-medical mission.

But as unskilful dramatists often manage their plots so awkwardly as to allow the catastrophe to be anticipated, so have the managers of this spectacle been sufficiently maladroit to let the public into all their secret. The event, if the performance be allowed to proceed, is a matter of the simplest inference; it is a foregone conclusion.

M. Rostan stands first on the list, with the cipher 26 attached to his name. M. Cayol comes next, estimated at $24\frac{1}{2}$ ("mark the $\frac{1}{2}$," says one of the journalists, "how conscientious and scrupulous it looks!"). MM. Chauffard and Piorry are set down at 23; and the rest of the candidates have ciphers variously lower. It might seem, at first sight, that it were still possible for some of the competitors just mentioned to retrieve their deficiency, and to have a fair chance with M. Rostan; this, however, is not the

case. From the nature of the regulation, which requires that the cipher of the first test shall be doubled by the result of the subsequent ones, the chance, even of the second candidate, is reduced to a moral impossibility; while, for the remainder, success is both physically and mathematically put out of the question. M. Cayol even declines to enter the lists any longer. In a bold letter which this gentleman has written to the members of the jury, he denounces their proceedings on this first trial as "an indecent mystification, both for the candidates and the public." He enters at considerable length into a calculation of the probabilities which might be supposed to remain open to him; he shews them to be perfectly illusory, and adds, among other expressions of opinion equally strong—" *Il est donc évident que ce Concours n'est qu'une déception et un mensonge; c'est une élection honteusement déguisée sous les apparences d'un Concours!*"

The reader may well imagine that M. Cayol writes under feelings of peculiar bitterness, because, for eight years, he held the very chair for which he has now offered himself a candidate,—having been dispossessed of it after the revolution of July: but the language of the other dissentients is not much less bitter, and the terms in which the subject is treated by some of the ablest French journalists, leave no room to doubt of the excitement and vexation produced by the whole affair among a large portion of the medical people of Paris. "Away, henceforth," says the *Journal Hebdomadaire*, "with those fine words, *publicity* and *concours*; they mean nothing,—they *are* nothing, upon the lips of those who use them, but a cruel irony, the bitterness of which the public can feel with an indignation not easily to be forgotten. By a jesuitical decision, the substance of the Concours is annihilated, and election alone is left

with all its disgusting pliability: it is a wretched farce, played half behind the scenes and half in the light of day, and intrigue and coterie perform the principal parts. It is the play of the *doctrinaires*, subtly played. All confidence in the thing is henceforth abolished: we have to deal only with a vain and colourless shadow!"

On the whole, it is quite evident that this luckless Concours has produced what our continental friends call an *imbroglio*,—but what we might denominate, in our homely phrase, a game at loggerheads. We do not mean to express an opinion in behalf of either party; we know not which is right or which is wrong; nor have we either leisure or inclination to fathom the intrigues which there is but too much reason to suspect are carried on most disgracefully in some quarter. Meantime we look at the occurrences with no small interest, as affording us a practical lesson of the working of this much-lauded method of appointment: for we must recollect that this is the boon which some of our pragmatist reformers would fain confer upon us, in their kind solicitude for the new-modelling of certain institutions in this country. They may tell us, perhaps, that what we have described is but a gross abuse of the Concours, and that we cannot argue from that against its manifold excellencies. It is sufficient for us to know that it is liable to such abuse, even where it is guarded by the patronage of government, the participation of the academies and the faculty, and by the zealous vigilance of the majority of the medical public. As we have formerly said, so say we once more: the principle of the Concours, as a mode of attesting merit, cannot well be disputed; but it is an abstract principle—from all we can see, very unmanageable in practice, while so very shewy and attractive in theory. It may apparently be applied with advantage, as it generally is

in France, in the appointment of pupils to the minor offices about the hospitals; but to propose it as a suitable method for filling up high and trustworthy places, cannot but be considered by reasonable people as not a little chimerical and absurd.

THE INFLUENZA.

THE alarmists have begun to raise the most absurd and groundless apprehensions in the public mind, on the subject of the present epidemic, and we hear of maladies of all kinds and of all colours that are to follow it, but especially of the "white plague," which is at once the newest and most dreaded. We are told that this visitation is to come from the east, in the track of the influenza. Now we have received very recent medical journals from Berlin, and we have examined those of Paris, into which news relating to such matters is always speedily copied, but in neither have we been able to find any thing to justify the coming of any pestilence; on the contrary, the only form of disease of any considerable prevalence seems to be the *grippe*, or influenza, such as we now have among us, and occasional cases of cholera and dysentery. But again, we are told that the records of past epidemics shew that visitations of plague and other malignant diseases have been generally preceded by influenza. We take leave to deny this. Influenza, exactly such as the present, has been known almost as long as we have any medical records; it was particularly prevalent in the fifteenth and seventeenth centuries, but was scarcely heard of in the sixteenth: thus it traversed Europe in 1510, 1557, 1564, 1580, and 1591; then we lose it till 1675, but have it again in 1709, 1732-3, 1743, 1762, 1767, 1775, and 1781-2. Now a reference to the chronology of other epidemic visitations will shew that no such proximity existed between them and the above, as to admit of their being looked upon either as cause and effect, or in any other light which would lead us to apprehend that the appearance of the one is likely to be followed by that of the other; indeed, the seventeenth century (in the course of which influenza appeared only once) was remarkable not only for the "great plague" of London,

but for three other of the most formidable epidemics ever witnessed in this country.

As to the rest, so far as regards the metropolis, the influenza has been "plague" enough, without looking for another; it has been a hundred-fold more prevalent than cholera was, and we are inclined to believe, has proved fatal within the last fortnight to a greater number of persons than that disease carried off in London within an equal period. Certainly this holds good with respect to the upper and middle classes of society, among whom a large number of aged persons have fallen victims to it. The increased mortality of the metropolis during the present epidemic, is strikingly exemplified by the weekly accounts of burials; that ending April 16, exhibits an increase over the preceding, of 266; that ending April 23, another increase upon the above, of 209; that of May 1, a farther increase of 165, — making the entire increase in the number of funerals last week equal to 640, and this, too, within the limits of the bills of mortality. The epidemic is now, however, rapidly on the decline, though a considerable number of relapses have occurred, and many continue to linger under its effects.

ters of peripneumonia notha, and the lungs becoming oppressed with a profusion of mucus, which he was unable to expectorate.

The character of Dr. Babington was probably as nearly without fault as is consistent with human nature. Benevolence was most strikingly depicted on his countenance, and it was also the leading feature of his mind. We allude not to mere sentiment, or feeling, but to an active principle of philanthropy, which led him to do all the good he could to others: thus we know that some of the last visits he ever paid—and at a time when he was himself suffering severely from the epidemic—were to patients from whom circumstances prevented him from accepting any remuneration. On a future occasion we trust we shall be able to give some particulars of his life: meantime, in announcing his decease, we offer our humble tribute to his moral worth. No man in our profession was more extensively known—no man was more universally respected—none will be more sincerely regretted. It was in contemplation to have had a public funeral, in honour of the deceased, but this proposal has given place, and we think judiciously, to the intention of offering a more permanent tribute to his memory.

DEATH OF DR. BABINGTON.

WE lament to place on record the death of Dr. Babington, which took place on the 29th ult., at his house in Devonshire-street, in the 77th year of his age.

Dr. Babington, in common with all practitioners in extensive business, had been very much harassed during the last few weeks, and was prevented, by the demands made upon him by others, from giving to his own case the repose and care which it required. Though labouring under cough, attended with great debility, he yet continued to visit his patients on Wednesday the 24th, till seven o'clock in the afternoon. He was then very much oppressed, and extremely weak; but a committee for preparing the new Pharmacopœia having been appointed to sit at his house that evening, he insisted on joining it, and was occupied at what proved the last of his professional labours till eleven o'clock. He then went to bed exhausted, became delirious, and was next morning in a hopeless state, the chest affection rapidly assuming the charac-

SOCIETY OF APOTHECARIES.

WE understand that it has been determined by the government to bring in a Bill, by which the right of practising in England will be given to the members of the Scotch Colleges.

CLINICAL REPORT OF ACUTE DISEASES,

Treated at the Hospital for Children in Paris during the first three months of 1833.

BY M. BOUNEAU.

Diseases of the Respiratory System.

Owing to the rapid alternations of temperature which occurred during the first portion of the year, the respiratory organs were those chiefly affected. First in the list we may place bronchitis, which has been met with in every form and variety. With respect to intensity, it was sometimes accompanied by general fever, and sometimes with complete apyrexia;

as to situation, at one time it was confined to the larger bronchi and the trachea, while at others it occupied the ultimate ramifications of the air tubes; finally, with respect to its nature, it was sometimes a simple mucons flux, at others an acute inflammation, with pain beneath the sternum, and in some the cough was convulsive. Laryngitis occurred particularly as an accompaniment of the exanthematous fevers, especially small-pox and measles. In three cases croup came on, which proved speedily fatal. In some of these cases there was membranous effusion found on post-mortem examination. Inflammations of the lungs and pleura have been very frequent. Gangrene of the lungs was found in three instances. Pulmonary hæmorrhage is not common in children; two cases of it, however, were met with this quarter; the first in a boy eleven years of age, who had every symptom of an excavation under the right clavicle; the second, also with vomica, sunk under a violent hæmoptysis during the interval between two of the visits. The presence of tuberculation has been ascertained in a great number of children. In order to give some idea of its frequency, it may be mentioned that, of fifty subjects examined after death during the three months in question, twenty-three had tubercles in the lungs and various other organs.

In the present report we shall confine ourselves to the inflammation of the lungs, which has almost constantly yielded to an emollient, antiphlogistic, or antispasmodic treatment, according to the nature of the case; and we shall first shew the results of the employment of large doses of tartarized antimony.

CASE I.—Symptoms of Inflammation of Pleura and Lungs in a Boy of 15. Bleeding—Large Doses of Tartarized Antimony—Recovery.

Vidal, aged 15 years, of strong constitution, and never having had any severe illness, was seized during the night of the 24th of January with a violent rigor, which lasted an hour, and was followed by intense fever, with cough, and pungent pain in the right side of the chest, augmented by coughing and inspiration: these symptoms continued next day, and the patient was brought to the hospital in the evening (25th.)

26th, morning visit.—Patient lying on his back; countenance flushed; general headache, without ringing in the ears or any disturbance of vision; heat of skin raised; pulse 100, hard; respirations short, 42 in the minute; dry cough; acute pain on right side of chest. Behind, the respiration every where free; anteriorly, slight mucons rattle under the clavicles.

Bleeding to three palettes; gum-water; low diet.

27th.—Blood shews a thin buff; pulse 96; respiration 32; cough and pain continue; some expectoration of viscid mucus, mixed with air. Expansion of lungs more feeble on right than left side.

Four cupping glasses to the right side of chest.

28th.—A considerable quantity of blood obtained by the cupping; the expectoration adherent to the vessel; pulse 90; crepitating râle over the upper part of the right lung.

Six grains of tartar emetic in eight ounces of aromatic potion; a spoonful to be taken every hour.

29th.—Nausea, followed by one fit of vomiting; no stool; pulse 84; respiration 32; pain in axilla and right breast; bronchophony; no crepitous râle; expansion of lungs weak beneath, and imperceptible above; respiration puerile on left side.

Six grains of tartar emetic; emollient lavement.

30th.—Face red; pulse 108; dyspnœa intense; inspirations 64; cough more frequent; voice hoarse; pain about the throat (nothing can be seen to account for this on examining the parts); tongue large, moist, white in centre, red at the point. Has taken all the potion. No nausea, vomiting, nor stool. Auscultatory signs as yesterday.

Same medicine; inhalation of emollient vapour.

31st.—Pain of side has disappeared; pulse as yesterday; respirations 48; no nausea nor vomiting; one stool.

Repeat.

Feb. 2d.—Pulse 92; respiration 25; tongue has lost its redness; respiratory murmur feeble, posteriorly on the right side, but without any râle.

Four grains of Tartar Emetic. Chicken tea.

3d.—Convalescence continues.

Omit Tartar Emetic.

6th.—Pulse 84; respiration 22; cough nearly gone.

14th.—Discharged cured.

In the preceding case the patient was seen soon after the attack, at which time the pleura only seemed to be implicated. The bleedings on the first and second days not only did not arrest the inflammation, but suffered it to spread to the lungs. The stomach soon became reconciled to the tartar emetic, and vomiting only took place the first day. Though the patient complained of pain in the throat, there

were none of the pustular appearances described by M. Gasc and others.

CASE II.—*Symptoms of Inflammation of Lungs in a Boy of 10. One Bleeding—Large Dose of Tartar Emetic—Recovery.*

— Brient, aged 10 years, of good constitution, was seized, on the 16th of March, with general indisposition, and pain in the left side of the chest. In the evening vomiting came on, and recurred during each of the next three days. Fever; frequent cough. No treatment was employed till the 20th, when he was brought to the hospital.

21st.—Lies on the right side; face flushed; headache; tongue red at the edges—tendency to become dry; much thirst; constipation; skin hot; pulse 120; respiration 56; very frequent short cough; no expectoration; pain over the whole of the right side of chest; bronchial soufflet over nearly all the back part of right lung; crepitating râle above.

Bleeding to two palettes; gum water; laxative clysters.

22d.—Blood shews a very thin buff; pulse 96; respiration 45; cough, &c. as before.

Potion containing eight grains of Tartar Emetic.

[After the two first spoonfuls, vomiting was excited, and the nurse discontinued the medicine from twelve till four o'clock, when it was resumed. No return of vomiting.]

23d.—Pulse 108; respiration 36; crepitating râle over the right lung, except at the subspinous fossa, where it is bronchial.

Potion with six grains of Tartar Emetic.

24th.—Cough less frequent; pulse 112; respiration 40; no vomiting nor purging.

25th.—Medicine borne well; some quiet sleep; pulse 88; respiration 26; pain of side gone.

26th.—Three liquid stools; no vomiting; right lung begins to expand.

Tartar Emetic suspended. Potion containing 2 drachms of Syrup of Poppies.

31st.—Discharged cured.

Resumé.—Other cases are related, of which, however, the following is a resumé. The tartarized antimony was administered to eight children labouring under pulmonary inflammation of different degrees. Five of these, who were perfectly well up to the date of their attack, recovered under the use of the medicine; it failed in two, placed under unfavourable circumstances, and in whom there was tendency to tubercles. The eighth died of an accidental, superadded disease. It is to be kept in mind, that inflammation of the lungs is

much more severe in infants than in adults; that it is almost always mortal in very young infants, and that the mortality in acute diseases, at the Hôpital des Enfants, is almost always one in three.—*Gazette Médicale.*

LONDON HOSPITAL.

Case of Excision of a Large Portion of the Lower Jaw,

By MR. ADAMS.

APRIL 24th.—Henry Curnon, æt. 42, applied to Mr. Adams, at the London Hospital, five weeks ago, in consequence of a large tumor extending into the mouth, and connected intimately with the right side of the inferior maxillary bone. The tumor presented a reddish aspect, and was divided by a fissure into two portions—one passing into the mouth, and the other pushing out the lower lip from the jaw. The part within the mouth was somewhat moveable, and was attached by a basis of no great breadth, so that it might without much difficulty have been removed; the other portion involved the horizontal ramus of the jaw, from which the whole disease evidently sprang. The tumor was exceedingly vascular; the greater number of the teeth of the diseased side were gone; the anterior and lateral incisors were displaced; and the two last molar teeth were so far displaced that one was pushed anterior to the other.

The man stated that he had formerly been the subject of syphilis, when 21 years of age; that he had taken mercury, by which salivation was induced, to which he attributed a disease which had evidently affected the nasal bones, for they were considerably depressed from the loss of part of the septum. He said that the disease commenced about nine years ago, after the removal of a tooth in consequence of the toothache, and that the jaw gradually enlarged; that a tumor also sprang from it towards the mouth, which was removed by a surgeon two years ago. There was considerable bleeding after the removal, which soon subsided. A similar growth soon made its appearance, and has been increasing rapidly ever since. He was admitted into the hospital on the 22d of April, the disease having advanced rapidly since his first application. Ulceration had taken place from pressure against the incisor teeth. A gland was found slightly enlarged in the neck. The man was in apparently good health, and the only inconvenience he experienced was from the difficulty of getting food into his pharynx, from the size of the tumor. He came in purposely for the removal of the diseased

mass, which he had been recommended to do when he first made application.

Mr. Adams performed the operation in the following manner:—Two incisor teeth having been extracted, the operator made an incision from the angle of the mouth to the angle of the jaw, on the right side, and having detached the integuments from the surface of the tumor, and from the horizontal ramus of the inferior maxilla, a groove was made with a saw at the symphysis, and the blade of a scalpel was passed beneath, so as to detach the soft parts. With a pair of strong cutting forceps (the same used by Mr. John Scott for the removal of the superior maxillary bone), an attempt was made to divide the symphysis. It was found impossible to complete the section of the jaw in this manner; the saw was again applied, and the division was accomplished by the forceps. The next stage of the operation consisted in the division of the bone just above the angle, which was accomplished in a similar manner, but with much greater facility. The tumor was then readily dissected out by detaching the mucous membrane of the mouth, cutting close upon the tumor. A lymphatic gland was then dissected out, and the operation was finished with the loss of a very small quantity of blood; the only arteries requiring a ligature being the inferior coronary, the sublingual branch of the lingual, with some muscular branches of the internal maxillary.

The parts were brought accurately together, and retained in apposition, partly by pins and the twisted suture, and partly by the interrupted suture, with adhesive plaister and a bandage lightly applied. The man walked from the theatre, apparently little affected by the operation.

He was ordered 40 drops of Laudanum, and 20 drops every half hour, until sleep was procured; the parts were kept cool by lint dipped in cold water.

On the following morning the man had passed a good night, and had a little fever.

He took Ol. Ricini, $\mathfrak{z}\text{j}$., and Mist. Salin. 4tis horis.

April 27th.—The wound was dressed, and seemed to have completely adhered. The pins were not loose; they were therefore allowed to remain, and the greater number of the sutures were also left.

Section of the Tumor.—The horizontal ramus of the jaw was sawn through from the bas, and a section was made of the tumor; a great portion of the walls of the inferior maxilla were absorbed, there being merely the remains of them found here and there; the growth had apparently commenced in the cancellous texture of the bone, and had made its way towards the

alveolar process, which was completely removed; it had then pushed itself towards the mouth in one direction, and in the other had made its way towards the cheek, producing a gradual thinning of the anterior plate of the jaw. The disease had not involved the ascending ramus. The tumor, on division, presented a white gristly appearance, in some parts being more fibrous than in others. A glairy fluid, like thickened synovia, exuded in different parts, and at one spot a considerable quantity, of a jelly-like substance, was seen. It had externally a lobulated aspect, and the mucous membrane of the mouth was reflected over its base.

The patient is doing remarkably well.

By DR. ELLIOTSON.

—
DISEASES OF THE CHEST.
—

ASTHMA.

BEFORE I speak of organic diseases of the lungs—those in which there is a new deposition, or a transformation, or lesions of the substance—I will consider functional diseases of these parts; and I will speak first of asthma, and then of hooping-cough. Asthma is often connected with bronchitis and hooping-cough, and very often with inflammatory diseases, but not necessarily so. Both asthma and hooping-cough are frequently unconnected with inflammation, nor is there any appearance after death that will explain the symptoms; they are frequently specific and functional diseases.

Definition.—By asthma is meant a spasmodic difficulty of breathing, situated lower down than the larynx and trachea—a spasmodic affection of the organs of respiration, below the larynx and trachea. You will recollect that it is frequently united with organic diseases—frequently united with inflammatory states—frequently merely the result of irritation; so that you may have it without any organic disease, or any inflammation at all.

Symptoms.—In a case of asthma—pure genuine asthma—you have a violent sense of constriction of the chest, with a loud wheezing respiration, heard without putting your ear to the chest, or employing a stethoscope. You hear a patient at some distance, wheezing and breathing for his

life. Such an attack as this is soon accompanied by a short and difficult cough; but as the sense of constriction goes off, the cough becomes freer and deeper, and there is some expectoration.

During such an attack as this, the face is pale, elongated, and pinched; the nose and extremities become cold; the pulse is found to be small and quick, and frequently I have observed it to be irregular. The skin throughout the body becomes rough, from the retrocession of blood from it; horripilation takes place; the patient looks as if he were dying; he is gasping for breath, cold, and pale, and in such an agony, from the want of breath, that you would think him dying; yet in the greater number of cases there is no danger whatever. Such an attack as this may last only a few minutes, or it may last several hours. It generally takes place in the middle of the night. The gout, when it first attacks an individual, generally does so in the middle of the night—that is to say, at two or three o'clock in the morning; and this is likewise generally the case with asthma. When it first invades, the patient jumps up in bed, throws off the clothes, draws aside his curtains, if he have any, frequently goes to the window and throws it open, and also the door, and stands at the window to get as much air as he possibly can. After a certain time he finds that he breathes more easily, can take a deeper inspiration, begins to cough deeper, begins to expectorate, and then he goes to bed again a great deal better. Very often at the same time the next night the scene is repeated. When a person is subject to this occurrence very often, the breathing for the most part is not quite free in the intervals; it is generally difficult; the patient feels that all is not right; and at the same time there is generally a great degree of flatulence. A large quantity of wind is made undoubtedly in the stomach; it cannot be generated by any simple chemical process,

that is out of the question, because a person in this condition, just like an hysterical woman, in a moment, from not having been distended at all, becomes filled with wind, and sends forth torrents as if there were no end to it; and this occurs without any thing in the stomach promoting the production of it. A great quantity of wind is disengaged from the stomach and intestines; but I think there can be no doubt (and John Hunter was of this opinion), that it can be secreted like fluid; for you see a woman in a moment, from a passion of the mind, swell out and pour forth torrents. It evidently must have been generated at the time; a chemical process of course could not have been so instantaneous. This will be the case whether there be any thing in the stomach or not; and I believe the wind in these cases is always inodorous. The wind—the gases from the alimentary canal—have been analysed by the French, and their nature is ascertained from the contents of the stomach and intestines, an account of which you will find in Magendie's work; but whether this wind has been analyzed I do not know; I think not. At the same time there is generated a large quantity of fluid; patients generate both wind and water. The water is pale, and it is as genuine water as can come from the body; it is quite pale, and in immense quantities, containing very little saline or animal matter. They are as pure specimens both of wind and water as can be produced, I suppose, from the animal body.

Premonitory Symptoms.—Some persons have these attacks only at certain seasons of the year, and some only in particular places. If they be subject to the affection, they are rendered far more liable to it by eating what is ill suited to their stomach—eating articles which they have found will not agree with them. Sometimes indigestion precedes an attack of this description; sometimes there are symptoms of the nervous system, such as sleeplessness and headache; and sometimes there is a great itching of the skin. These circumstances occasionally precede the disease.

Attacks persons of all ages.—The occurrence of the disease is very various; some have it only for a few nights, and some for many weeks. It is a disease which attacks all ages. I have seen it over and over again in infants at the breast, where, from the very slightest degree of bronchitis—the slightest catarrh, they have been seized at different periods of the day with violent wheezing, and that wheezing ceases almost as suddenly; and therefore I have no doubt it is asthma. I have seen several instances of it, as I suppose, in boys below puberty and above it, and very frequently it attacks

young adults. The recurrence of the disease may last many years; persons may be subject to it for many years, and then it may cease entirely, without any consequences whatever—without being followed by any other disease. A patient shall at one period of his life entirely cease to be asthmatic, and this cessation of the disease for good may be at all ages. At any period of life an asthmatic person may cease during the rest of his existence to be asthmatic. With some persons it occurs only in particular seasons, from particular circumstances, and from particular states of the weather; but with some, the tendency to it is so strong, that they are sure to have it wherever they are. There are always exciting causes enough to produce the disease in them, so extreme is their liability to it.

Occasionally attended by pain.—I have sometimes seen it attended with very great pain; there has appeared to be a violent spasm of the respiratory muscles, so that patients have had violent pain; and yet, without any bleeding, simply from stimulating remedies, this pain has ceased.

Varieties.—Although this which I have now described is the regular form of the disease, yet, like epilepsy, it sometimes puts on a very great irregularity. Some persons in the fit will make a crowing noise; some will have a number of successive deep inspirations, and then they will suddenly cease to breathe. There is every sort of variety that you can imagine; but still, no doubt, it is all deserving of the name of asthma.

Frequently combined with other diseases.—The disease is literally pure spasm, and does not necessarily depend upon any thing organic; but it may be combined with any inflammatory disease of the chest, and it may be combined with any organic disease of the chest; even the slightest pressure in some people will cause this affection. I believe I mentioned formerly, that Mr. Lawrence has described a case in which violent paroxysms of asthma were induced simply by an aneurism of the innominata, causing the least possible degree of pressure upon the trachea.

The disease with which asthma is most commonly united, is chronic bronchitis. When persons labour under the latter affection, besides constant difficulty of breathing, they are subject to great aggravations of it in the course of the day, from time to time, particularly at night. As in this case they spit up a great deal, the affection is called *humoral asthma* by the old writers. But you have chronic asthma continually without this disease; you may have it without this tendency to a spasmodic affection. Sometimes it is united with pleuritis and peripneumonia, and on

bleeding such patients you have buffy blood; but in a case of genuine asthma it is rare for the blood to be buffy; I do not know that it ever is. It is frequently seen united with diseases of the heart; but then it is to be remembered, that nothing is more common in organic diseases of the heart than for chronic bronchitis to exist. The heart is seldom organically diseased to any extent without the bronchiæ being more or less inflamed.

Diagnosis.—The disease is easily distinguished from hydrothorax, because if you strike all over the chest you have a clear sound; and if you listen, you have respiration all over the chest, which you cannot have if any part of the cavity be filled with water. You distinguish it from bronchitis by the absence of sonorous and sibilous rattle, excepting in the upper parts. Down below, throughout the rest of the chest, you hear not those peculiar sounds of bronchitis—or, if you do hear something like them, they suddenly cease, they go off, and then there is the sound of health—but while bronchitis lasts you have sonorous and sibilous rattle, and these only subside either by art, or the disease itself ceasing. In general, you will hear a loud respiratory murmur all over the chest, louder than it should be. The absence of other diseases, together with the suddenness of the attack,—the suddenness with which it goes, and its extreme aggravation from time to time, will enable you to form your diagnosis.

Prognosis as to the Paroxysm.—The prognosis in the disease, so far as the paroxysm is concerned, is generally good; but I have seen people die from pure spasmodic asthma. I recollect that last year a young man was brought to the hospital in a great fright, who had been asthmatic, and, when I saw him first, he was dying. He could only breathe while on his knees and elbows; he was obliged to be in that posture to breathe at all, and no signs of any other disease were found during life. He was cold and pale, and the pulse was not to be felt; and in the course of two or three hours he died. He had been asthmatic; but this fit produced such an asthmatic state that he did not survive. On opening him no signs of disease were found; but the lungs were all distended, had lost their contractile power, were unable to collapse, and they were as light as a feather. I have read accounts of this occurrence, but it is a rare thing indeed.

Prognosis as to the Termination of the Disease.—The prognosis, however, must be unfavourable as to the termination of the disease. Some persons will be liable to it for life, if they live in particular situations, in spite of all that you can do. You have a prognosis to make of the paroxysm, and one as to the duration of the disease—the

one is favourable, and the other unfavourable; but then the prognosis respecting the distant event must depend upon the existence of other diseases. The prognosis, so far as the asthma is concerned, is not bad. People labouring under this affection often live to a great age, and the disease often ceases of itself. But you must always consider in these cases, that there may be some other disease—chronic bronchitis, chronic peripneumonia, or disease of the heart—but if not, there may be a tendency to phthisis; and therefore all these things must be taken into the account in forming a prognosis. Dr. Heberden mentions a curious case of the cessation of asthma after it had existed some time; and not only a curious case, but other cases of persons ceasing to be suddenly asthmatic, and never having another attack, though they lived thirty years afterwards. I have myself known instances of its cessation after having existed a considerable time. But we can never prognosticate this. If it turn out so it is all very well; but I think we have no means whatever of saying that it will thus terminate.

Predisposing Causes.—The predisposing causes of the disease are not known. Very often it attacks those who are thin and pale; but they have pure, simple, spasmodic asthma. It as frequently, however, attacks those who are short and full—bulky; and these generally have a combination of asthma and chronic bronchitis; they expectorate a great deal, have humoral asthma. Of the real predisposition, however, we certainly do not know the nature. We know it is often hereditary; many have asthma whose parents, one or both, or whose grand parents, have had the disease. It runs in families.

Exciting Causes.—With regard to the exciting causes of the disease, they are, in general, cold and damp, and especially fogs. Some persons have it only in cold weather; others have it only in damp, foggy, moist weather: but there is a great variety in this respect. Some persons have it only in summer, and are all the better for cold weather; and some never have it but in particular situations. Most people are better in the country, if it be a dry place; and some are better in London; so that persons who have made their fortunes, and retired to the country, have become asthmatic, and have been obliged to return and live in Thames Street again. I have read of cases where parties have been obliged to go back to an old house in Thames Street. I only mention it, because I recollect a particular street, and that as damp and dirty a street as there is in London. In some persons this disease is only induced, as it would appear, by particular exhalations from the vegetable kingdom—the emanations from

grass in flower. These are the people who have asthma only in summer; but by far the greater number who have the disease aggravated in winter are pretty well in summer: some, however, are never asthmatic till about May or June. I should think all these cases may be resolved into that particular form of disease which has been called *hay fever*, or *hay asthma*. In some cases there is a simple spasmodic affection of the breath, and in others there is a violent catarrh united with the spasmodic affection. This is a disease which has only been noticed of late years, and respecting which I have some curious facts to adduce.

CATARRHUS ÆSTIVUS, or HAY FEVER.

Certain writers have spoken of what they call a summer cold, *catarrhus æstivus*. The first medical composition that I read upon the subject, and the first that I ever knew to exist, was by Dr. Bostock, the celebrated chemist. It was from him I learned that some writers spoke of *catarrhus æstivus*; but I do not know to whom he alludes. Dr. Bostock states, in one of the volumes of the *Medico-Chirurgical Transactions*, that at a certain time of the year he begins to sneeze—he has a running of the eyes, and all the symptoms of catarrh—and that these continue for a certain length of time, wherever he is, and whatever he does. In a second paper, published by him about three years ago in the same work, he again refers to the subject, and relates his own case at considerable length. Before that time I had heard people talk about hay fever and hay asthma, but I could not comprehend what they meant. I was told that certain distinguished personages had *hay fever*. It appears to be quite an aristocratical affection, not at all visiting hay-makers, or those who have to do with hay and straw. I never met with such a thing in practice; and it appeared to me to be a highly gentleman-like, and indeed, I may add, noble affection. I could not tell what to make of it, and I disregarded it entirely, supposing it to be a sort of aguish or hypochondriacal affection, of which those who had little to do frequently became the subject. I had no idea that it was an affection of the chest till I read Dr. Bostock's paper. I happened, however, last year, to be attending in a family, where the mother of the lady was said to have been the victim of it many years. She was a very sensible and superior woman; and she stated, that at a certain time of the year, when the grass came into flower, she was dreadfully distressed in breathing, and was obliged to leave her house, and go to as barren a place as she could find at the sea-side, and there she obtained comparative ease. She told me this had been the

case for many years; that she had tried every thing in vain; that nothing did her good. She was not the only member of the family afflicted with it, for an uncle, some of her nephews and nieces, and some of her cousins, laboured under it. It was decidedly an hereditary family matter.

As there are some curious features in these cases, I alluded to them in a clinical lecture delivered at St. Thomas's hospital last year.* I knew that that course of lectures was published, and I thought that the shortest way to make the thing known was to mention it then, and away it would go. The consequence was, I received several exceedingly kind letters from gentlemen unknown to me, giving me facts upon the subject; and as the matter is very interesting, I will read a few of them.

Mr. Gordon's description of Hay Fever.—One of these letters was received from Mr. Gordon, a surgeon residing at Welton, near Hull, Yorkshire, who stated, that in the *MEDICAL GAZETTE* for 1829 he had described the very same thing. I was not aware of it at the time, or I should have felt it a great pleasure, as well as my duty, to refer to it. He says,

"I have this evening received the 186th Number of the *LONDON MEDICAL GAZETTE*, dated June 25th. It contains the report of a clinical lecture which you delivered at St. Thomas's hospital in March last, on the subject of hay asthma.

"In consequence of your expressing a wish to receive information on this extraordinary complaint, I have taken the liberty of troubling you with this letter. I beg leave to state, that I have witnessed several instances of hay fever and hay asthma; and, in the 87th Number of the *LONDON MEDICAL GAZETTE*, bearing date Aug. 1st, 1829, I published a short account of the nature, symptoms, causes, and treatment of these curious disorders. In that memoir I have observed, that the best preservative against their attack is the cold shower-bath. For the last two seasons, however, whilst employing this, I have administered the *sulp. quinine* with the *sulp. ferri*; the former in doses of two or three grains, the latter in doses of one grain, three times a-day. The success which has attended this prophylactic treatment has exceeded my highest expectations. With two of the most severely afflicted of my patients on whom it has been tried, it has answered so effectually, that both of them have this year been able to walk through a rich meadow without suffering in the slightest degree; although formerly, if they had ventured out into such a situation, they would have brought upon themselves all the agonies of spasmodic asthma.

"I hope you will do me the honour to

* *Med. Gaz.* vol. viii. p. 411.

read over the description which I have given of hay asthma in the above-named medical journal,"—and so on.

"The symptoms which I have related were taken principally from the cases of * * * * *. These two gentlemen have been annually attacked with hay asthma for the last fifteen or twenty years. They consulted Dr. B. and most of the eminent English physicians, as well as several practitioners on the Continent, but derived no relief from what was prescribed for them. By means, however, of the shower-bath, the quinine, and iron, they have for the last two years obtained a complete emancipation from their tormenting disorder."

Another description of Hay Fever.—Another letter is from a practitioner at Bristol, who says,

"I knew nothing about hay fever, as any definite disease; but your description of it is, with little exception, a very accurate detail of what I have suffered every June for several years."—Here was a gentleman who had been ill every summer for several years without being aware what his particular complaint was.—"Were I not," he proceeds, "at the present time, annoyed by this troublesome affection, I should probably not have found leisure to give you the trouble of reading any thing on this subject.

"The attack generally begins with me the latter end of May, with great itching of the eye-lids, particularly at the inner canthi, from which I regularly, during this month, extract some cilia, which grow very near the cornea, and increase the irritation. My most troublesome symptom is sneezing: it is of a violent kind, and often continues till I have sneezed eight or ten times. The defluxion from the nostrils is most copious at these periods of the day, while, in the intervals, I have no catarrhal symptoms: the expectoration of clear mucus is also considerable. My sneezing attacks are sure to come on while I am visiting my patients, to my great annoyance. This comfortless state generally continues for five or six weeks, but is never sufficient to interrupt any of my employments, or render any confinement necessary, though I am always free from it when in the house. How far grass or hay have any thing to do with this affection I cannot satisfactorily determine. There are certainly several hay-fields within a quarter of a mile of my house. The air seems to make me worse, and an open window is my abhorrence while I am thus indisposed. Last week I spent an hour or two in a friend's hay-field, with a party of ladies; but the syllabub, the ladies, and the pastoral sports, had no amusement for me, and I was glad to get to a corner of

the park, where my streaming eyes and nostrils, and noisy sternutations, might escape both remark and commiseration. Certainly, during that afternoon, in the hay-field, was the worst attack I have had, but whether it was the air which was cooler than usual, or the hay, I could not tell. I must however confess, that my fancy on the subject has always leaned more to the effect of some subtle particles of an irritating nature than to the ordinary causes of catarrhal affections.

"My lungs are rather asthmatic; formerly I had a good deal of asthma. I have never found time to try any remedies, but shall certainly bear in mind yours, should I have this visitation next year."

Dr. Bulman's Cases of Hay Fever.—I have another letter from Dr. Bulman, of Newcastle-upon-Tyne, who has given me several cases, of which the following is one:—

"D. B., æt. 36, is of a spare but robust habit, and free from any constitutional or hereditary affection, except perhaps the gout. He has been liable since his seventh year, if not sooner, to annual attacks of the disease so ably described by Dr. Bostock, under the name of catarrhus æstivus, in the 14th volume of the Medico-Chirurgical Transactions.

"The disease invariably commences, about the second or third week in June, with a sense of uneasiness, heat, and itching in the tunica conjunctiva, but the itching is more particularly severe along the tarsus, and in the caruncula lachrymalis. On examination, this membrane is found to be considerably inflamed, but, except in the severer attacks, the inflammation does not extend to the eye-ball. The symptoms before mentioned are attended with watering of the eyes—increased secretion from the meibomian glands—a sense of fulness or rather distention of the eye-ball—intolerance of light—and weight in the forehead. The itching gradually increases in violence till it becomes almost insufferable, compelling the patient, notwithstanding every resolution to the contrary, to rub his eyes, by which it is always considerably allayed.

"In the course of a few days, but sooner if the patient has exposed himself to the sun, the inflammation extends to the schneiderian membrane of the nose, attended with itching and stuffing of the nostrils, increased secretion of mucus, and violent paroxysms of sneezing; which are also excited by dust of any kind, exposure to the heated external air, effluvia of new-made hay, and the odour of the beaflower—perhaps, also, by other odours.

"As the disease continues to advance, the membrane of the fauces and lungs is affected, giving rise to a sense of dryness

and extreme itching or pricking in the throat, and slight cough, with tightness of the chest, and difficulty of breathing; but there is little or no expectoration.

"There are several paroxysms daily, which commence with intolerable itching and tingling of the eye-lids, and are followed by the most violent fits of sneezing, accompanied by a copious discharge of mucus from the nasal passages; after which the patient obtains a longer or shorter respite; for the paroxysms recur at uncertain intervals, save that one invariably takes place about half an hour after rising in the morning.

"The tightness of the chest and difficulty of breathing, though sufficiently distressing, have seldom been very urgent; but on two occasions they rose to such a height that the patient conceived himself in danger of instant suffocation.

"In severe attacks the eye-lids become œdematous.

"During the whole course of the disease the patient is languid and listless, and, though restless, is averse to motion. His temper is more irritable than natural; but his pulse is scarcely, if at all, affected. His bowels are regular, and his appetite rather increased than diminished.

"The disease continues till about the end of July or the beginning of August, when it almost imperceptibly declines; and it is remarkable, that the patient is then able to expose himself to the hottest sun without the recurrence of any of the above detailed symptoms,"—shewing, of course, that it does not depend upon the temperature,—“and indeed, during the violence of the disease, exposure to the open air early in the morning, and in the evening after sun-set, causes but little inconvenience.

"The patient has had attacks of the disease in France, Switzerland, and Italy. In the two former countries it was as severe, but not more so, as in England; and it is extraordinary, that in Italy, notwithstanding he was daily exposed to the powerful sun of Rome, in the month of June, the disease, though it began earlier, was nevertheless considerably milder, and also of shorter duration, than elsewhere.

"Most of the internal remedies mentioned by Dr. Bostock have been tried, but in vain. Bathing in salt water, both cold and tepid, has been had recourse to. The former is apparently without effect; the latter has only seemed serviceable, inasmuch as it has relieved the tightness of the chest, and the difficulty of breathing.

"Of local remedies the only one which has proved of any efficacy is the ung. hydrarg. nitratis, properly diluted. This, though it occasions considerable pain when applied to the eye-lids, has always greatly

allayed the itching and smarting, and has even seemed, probably by being carried into the nostrils with the tears, to diminish the irritability of the schneiderian membrane, and hence lessen the violence of the sneezing, a most distressing symptom. The vinum opii was tried many years ago without any benefit, as in the case of Dr. Bostock.

"With respect to a residence at the seaside, it may be observed, that the only instance of the disease attacking the patient previous to the usual period was in the last week in May 1829, during hot weather, whilst he was residing for a few days in an airy house, situated on a cliff overhanging the German ocean. The attack, however, was slight, and lasted for two days only; but again returned at its usual period in June.

"As to diet, the patient is decidedly worse when living low.

"The above detail was written some months ago," continues Dr. Bulman, "and I am happy to state, that the patient almost entirely escaped the disease this year, by merely commencing, some time previous to the expected period of attack, to anoint the eye-lids at bed-time with the ointment, and bathing them occasionally during the day with a collyrium composed of rose-water and acetate of zinc, and after this had dried, smearing them with simple spermaceti ointment, to remove the stiffness left by the collyrium.

"I have only heard of one other example of this curious disease in this neighbourhood. The patient is a gentleman of fortune, and the instant he approaches a hay-field he is attacked. I have never been able to hear of the disease in the lower walks of life, though my situation, as physician to two extensive charities in this town, has afforded me ample opportunities of meeting with it, did it exist among them.

"I may add, that none of the patient's family—that is to say, neither his father, nor mother, nor brothers, nor sisters, though originally amounting to thirteen—were ever affected in the slightest way by this distressing complaint.

Mr. Poyser's Cases of Hay Fever.—There is another case with which I have been favoured by Mr. Poyser, of Wirksworth:—

"Mrs. H., of middle age, of a full and rather corpulent habit, has been subject for many years to this periodical complaint. The attack generally commences about the middle of June (the old time), sooner or later, according to the heat or closeness of the weather.

A sensation of heat and irritation is first experienced in the eyes and nostrils, accompanied with sneezing, fever, and rest-

lessness. These symptoms (if the complaint increase) are succeeded by a sense of constriction about the chest, aggravated very much by exertion, and increasing towards night to a regular asthmatic paroxysm. In the severer attacks of the complaint there is a permanent wheezing and difficulty of breathing, with an inability of moving, or of remaining in a recumbent position, and accompanied with pain, fever, quick pulse, and a great degree of general indisposition, lasting for some weeks, and leaving great debility, with an oedematous state of the feet, ankles, &c.

The treatment has been conducted on general principles."

To shew the hereditary nature of this affection, I will read a little more of Mr. Poyser's letter:—

"Mrs. P. A., also the mother of a large family, has had this complaint several years. The symptoms in her case resemble very accurately those described by Dr. Bostock, viz. a sensation of heat and fulness in the eyes, accompanied with redness and discharge of tears. These sensations go on increasing, and a fulness in the head is experienced, with irritation of the nose and violent sneezing. To the sneezings are added a farther sensation of tightness of the chest and difficulty of breathing, with a general irritation of the fauces and trachea. These symptoms are worse by paroxysms, and are often traced to changes of the weather and other causes; they do not, however, as in the instance of Mrs. H., go on to regular asthma. The complaint wears itself out toward the middle of July. This lady decidedly considers the cause of her complaint to be an emanation from the flowers of grass. It begins when grass comes into flower. There is a perceptible increase, or paroxysm, when she is exposed to these effluvia; and when the flowering time is over, she can go into a hay field with impunity, which she could not previously do.

"The father of this lady is immediately seized with violent and continued sneezing, inflammation of the nose and eyes, when he goes into or approaches a hay field, but the symptoms go off when he is removed from the smell of the hay. He therefore carefully avoids the exciting cause, and escapes the disease."

"Three of the sons of Mrs. A. are also subject to this disease, and the symptoms are similar to hers, though less severe. One of these young gentlemen is now at Geneva, and had the complaint there this summer. A younger son, a boy about 10 years old, is made asthmatic by the smell of Guinea pigs."

You see, therefore, what the character of this complaint is—that it is not merely spasmodic asthma, but excessive irritation

of the mucous membrane of the eyes, nose, and the whole of the air passages. It is a combination of catarrh and asthma.

I have no doubt myself whatever, that it arises from vegetable matter diffused in the atmosphere—that it is derived from the flowers of some plants—and that in a great number of instances it comes from grass. The lady to whom I have referred, and who informed me that she had had the disease so many years, told me that she was once away from home at an inn, where she conceived there was no danger whatever of being affected by the flowers of grass; but she was seized with a violent difficulty of breathing, and great irritation; and on looking out of a window, she found that there had just been brought into the inn-yard a cart load of hay. She told me also, as another proof that the affection arose from this source, that her children once came into the room after having been playing with hay, and instantly her breath became affected. She also informed me, as a still farther corroboration, that if she handled fresh hay her hands instantly became affected, shewing the morbid sensibility of her skin (skin, you will remember, is analogous to mucous membrane) to the flowers of grass. I have, however, a letter from this lady, in which she details the whole particulars of her case; and as it contains many interesting facts, I will read it.

Another case of Hay Asthma.—"I was first affected with the disease in 1798, and from that period have suffered annually from it more or less. It usually attacks me about the latter end of May, and continues till the middle of July, and sometimes till the close of that month; but this has occurred when the weather has been unfavourable, and the hay harvest has been particularly late. I have never suffered after the hay has been got in.

"The first symptoms are irritation of the nose, violent sneezing, and all the usual attendants of a cold in the head. These are succeeded by spasms affecting the breath, which have often been so severe as to threaten my life, and are the most distressing part of the disease. Violent irritation of the eyes, throat, and the whole interior of the head, has been experienced when passing by fields where hay was making, which symptoms have all disappeared very soon after entering a room, and excluding as much as possible the external air.

"I believe the complaint with me to arise principally, if not entirely, from the farina of the grass. It has commenced sooner or later according to the season; and my first symptom has generally occurred when walking in the fields, and not till the grass is in flower; and from that

time till the hay harvest is completely finished I suffer whenever I am exposed to the air.

"I have tried the sea air, and also London; the former I found most beneficial, although the latter was productive of considerable relief. Ramsgate and Harwich have suited me the best, which I attribute to the small quantity of grass grown in the neighbourhood, and to the bracing air, which has invigorated my general health. At all places by the sea, I have been immediately sensible when a land wind blew, and felt instant relief when it came off the sea again; and two years when this was the case, at Harwich, nearly the whole of the six weeks I spent there I suffered scarcely any inconvenience. I walked out daily, went frequently on the water, and bathed regularly in the sea. Other seasons I have been obliged to shut myself up entirely in the house, not to allow a window to be opened, or to permit any one who had been into the air to come near me.

"My children, in approaching me after being in the hay field, have often brought on a fit of sneezing, or a spasm of my breath; and this was once effected by their sitting down by me to tea, after playing in the barn where the new-made hay was stacked, some time after the season was over. Once, at Harwich, when walking on the shore, I became suddenly affected, which occasioned some surprise, as no grass was apparently near; but on the following day I found that hay was making on the top of the cliff at the time I was walking under it.

"At Cromer, two years since, I was suddenly seized with shortness of breath, &c., after the complaint had subsided, and all the hay finished in the immediate neighbourhood; and upon going into my bedroom, I saw an immense stack making in a yard near the house, and which had been brought there from a field five miles distant. In 1817 I was perfectly well till the grass was cut in our own fields, when my breath became so seriously affected, that it was thought necessary to remove me directly from the infected air; and I was with difficulty taken from my bed to the carriage which was to convey me to Harwich, twenty miles distant; and when I arrived there, I was so much relieved by the change of atmosphere, that I walked up with ease two pair of stairs to bed, and had no return of illness that season.

"In packing baskets with hay I have frequently had fits of sneezing, and tingling in my hands, and have every reason to believe that the seeds of the grass is poisonous to me.

"I have long ceased to have medical advice for the complaint, and by avoiding

the exciting cause as much as possible, and using palliatives on the first attack, I have of late years suffered less than formerly. I always confine myself entirely whilst the hay is making near me, and at other times walk with salts or some other pungent scent in my hand, and when I feel the irritation commencing, if I snuff it up, I can frequently keep off a fit of sneezing. My breath is relieved by sedatives, and smoking stramonium will always check the asthmatic spasms.

"My uncle, Mr. ****, of ****, and his son, were affected about the same time as myself; the former with sneezing only, and the latter with all the symptoms. They both attribute it to the grass; and the son is obliged to come to London when his hay is making. A cold season suits me best, and the symptoms are aggravated by a close air, which may perhaps arise from the obnoxious particles hanging in the air, and which of course are inhaled in larger quantities.

"The disease has certainly increased rapidly during the last twelve years, and has attacked persons of all ages. Most of those with whom I have conversed on the subject, believe it to be occasioned by the farina of the grass, or something to them poisonous which floats in the air at that time, and which comes when the grass begins to flower, and departs when the hay harvest is over.

"I have no disposition to asthma at any other period of the year; scarcely ever have a cold, or occasion to use a pocket handkerchief. My habit is relaxed, and I am always benefitted by a cold bracing atmosphere. I have occasionally found my breath considerably relieved by going out of the air into a crowded assembly, and from our own house in the country to one in a narrow street in the middle of a town."

It is conceived by some persons that it is the sweet-scented grass which is productive of this affection; at least many persons have decidedly been affected when they have gone near sweet-scented grass in flower; and some ascribe the greater prevalence of the disease now than formerly, and consequently the notice of the occurrence, to the introduction of some new species of grass into this country.

Treatment.—Seeing that the emanations from the grass, the pollen in all probability, was a compound, but whose constitution I myself do not know, I fancied that it might be destroyed in its composition, broken up, by the chlorides, the same as some animal matter. I therefore requested a gentleman who had the disease to try it, and he did so with the most perfect success. This was the first case that I ever saw of the disease. A gentleman came to

consult me upon it about three years before I saw the lady. I told him at once that I knew nothing of the affection, and I sent him away as he came, so that neither he nor I got any thing by the interview. I told him that I had heard of such a thing as hay fever existing among distinguished lords and ladies, but I could not conceive what it meant, and therefore I could give him no advice. I casually met him after I had read Dr. Bostock's paper, and I requested him, as a favour to myself, to try the effect of a solution of the chloride of lime or soda. I directed him to place it in saucers about the bedroom, to have rags dipped in it and hung upon the backs of chairs, to wash his hands and face with it night and morning, and to carry a small bottle with him, and repeatedly smell it in the course of the day. He complied with my request, and the result was highly satisfactory. The irritation of the ears (for in his case they also were affected), the tingling and the smarting of the eyes and nose all ceased; and by using this precaution he got through the summer exceedingly well. Whether the chloride acted by destroying the emanations, or by lessening the irritability of the mucous membrane, or of the skin, I do not know. The chlorides, if well diluted, diminish the morbid irritability of the surface, and therefore they might in this case have acted in that way; the treatment, however, was perfectly successful. The lady said that she had used every thing, but in vain; and I could not prevail upon her to try the remedy.

In consequence of making this known in the clinical lecture, it is said by Mr. Poyser that one of the sons of the lady affected with the disease employed the chloride of soda. Mr. Poyser says, "The chloride of soda has been of great use to this gentleman, removing at once the sensibility of the nostrils and eyes, and thus allaying the sneezing, cough, and inflamed and watery state of the eyes." But he adds, "Mrs. P. A. has not experienced any perceptible advantage from the chloride." Three out of four, however, did. When persons are subject to spasmodic asthma also, I should recommend them to breathe through water impregnated with the chloride; and a larger quantity ought then to be employed about the bed-rooms than when they have hay fever alone.

Ipecacuanha a cause of Asthma.—Some persons are peculiarly affected by other substances. Many persons have a peculiar susceptibility of ipecacuanha; this is by no means uncommon. If ipecacuanha be powdering in a chemist's house, some persons will be seized with a violent paroxysm on entering it. I have known an instance or two of this description. I heard

a physician say, that there was a case related on which he could depend—but I would not myself vouch for its accuracy—of a person who had such a susceptibility of ipecacuanha, that on entering a room and being seized with asthma, he declared that there was ipecacuanha about. It was at first denied, but at last some one recollected that there was a box of ipecacuanha lozenges in a table drawer. That was going very far; but it is a fact, that some persons are seized with asthma if ipecacuanha be near them.

Effects produced by the smell of different animals.—As I shall not have another opportunity of doing it, I may mention here, that other persons are peculiarly susceptible of various things. Some are affected by the emanations of an animal. You will remember that Shakspeare alludes to some females who cannot bear a sucking pig; and some cannot bear a cat; some are made miserable if a cat be near them. It does not produce asthma, but the emanation from a cat has such an effect upon them, that they are quite wretched. Mr. Poyser states, that a son of the lady who had hay asthma is made asthmatic by the smell of Guinea pigs. When he is in a room where they are, he is immediately seized with difficulty of breathing. I have a note from a gentleman, in which he informs me that a nobleman with whom he is acquainted, is affected by sneezing and asthmatic affections by coming in contact with a hare, or rather the fur of a hare, and remains ill for several days afterwards. He experiences great suffering whether the hare be dead or alive.

Hay Asthma not confined to the upper classes.—I have another letter on the subject of hay-asthma, from Brighton, but I will only read a portion of it. Dr. King says, "I know a member of parliament who has come to Brighton every summer for some years, in order to avoid the disease at home. A lady also comes from Clapham for the same purpose, and with the same good effect. The lady, however, whom I saw with it, told me that she knew a cobbler's wife who had it, and that several persons of the lower orders, to her knowledge, had the disease." Dr. King, in his letter, goes on to say, "Last year I met, at Lewes, a farmer's wife, subject to the same complaint, and obliged every hay season to take refuge in a town. She bears up against it as long as possible, shuts herself close up in her room, till a sense of suffocation comes on, as in common asthma, when she is obliged to throw open the window, by which she lets in a fresh dose of poison, and has the same routine to go over again, till she is obliged to fly. As soon as she quits the regions of hay, she experiences immediate

relief. I dined lately in company with a lady who went into convulsions as soon as her plate was put before her, containing some peas which had been boiled or dressed with mint. We carried her out of the room, and she did not feel quite well all the evening. Her daughter, who sat next her, was not similarly affected." These are circumstances worth knowing, because, if you were not acquainted with them, you might ascribe cases of this description to whim and fancy. It would be very odd if they were confined to the higher orders only: it is a thing exceedingly improbable. The fact is, the lower orders consider it as merely a common cold, and they do not apply for medical advice, being unable to pay for it, unless they are tolerably ill. They do not think of applying to a public charity because they are seized with a violent sneezing; or if they do, it is a solitary case, and is treated as asthma, the nature and causes of the disease not being known.

Curious cases by Laennec.—Laennec has no idea of it, but he mentions one or two curious circumstances. He says that the following fact was communicated to him by one of his colleagues, as affording a curious instance of nervous affection in a man not subject to asthma. "A man, 40 years of age, slightly hypochondriacal, but otherwise in good health, wished to go on horseback to pay a visit some leagues distant from his house. As soon as he left the town where he resided, which is situated in an extensive plain, he felt an immediate oppression on the chest, from the impression of the country air. He took no notice of this at first; but the dyspnoea having greatly increased, and being now attended by a sense of faintness, he determined to return. He had scarcely turned his horse when he found himself better; and in a few minutes he recovered both his breath and his strength. Not suspecting any relation between this momentary uneasiness and his journey, he once more attempted to advance, and was again soon attacked with the dyspnoea and faintness. On turning towards the town these passed off. After having made repeated attempts to proceed, and always with the same result, he finally returned, and in just as good health as when he set out. I have lately met (continues Laennec) with a case very analogous to the one just related, only that in this the symptoms were more severe and the cause different. Count H., a man of robust constitution, and, although now 82 years of age, still possessed of a degree of vigour unusual even at the age of 60, has been subject from his infancy to attacks of asthma, and is habitually somewhat short-breathed. Since

his fiftieth year he has had a slight cough, and in the morning a pituitous expectoration, intermixed occasionally with some yellow sputa. The asthmatic attacks have always been unfrequent with him, but they have invariably come on if any person has inadvertently shut his bed-room door, or if his night-lamp has by any chance gone out. As soon as either of these accidents occur, he immediately awakes with a feeling of oppressive suffocation, and after a few minutes he becomes insensible. On the occasions alluded to, the attack is got rid of by opening the doors and windows, lighting the candles, and carrying the patient into the open air." I presume it is the smell of the lamp which causes it, and perhaps the emanations from his own body—the smell of his own perspiration when he is shut up: that possibly is the case.

Causes of Asthma.—You see, therefore, that in many instances of asthma there is a violent external exciting cause; at least, unquestionably there is an external exciting cause, but it is very various in different individuals. A predisposing cause in many persons is bronchitis, and in others various organic diseases of the chest. In some persons, without any external excitement at all, without moisture or coldness, or confinement from the air, there will be an asthmatic paroxysm simply from an irritable state of the mucous membrane, and from organic disease itself. I have already alluded to one case, where, from the mechanical pressure of a small aneurism, a paroxysm came on independent of all external circumstances.

Treatment.—The treatment of this disease may be divided into two parts: one during the fit, and the other in the way of preventing its recurrence.

During the Fit.—In the fit, if the patient be plethoric, it may be well to bleed; but in general this is not necessary. One of the best things you can do is to give the patient a full dose of opium. A very large quantity is frequently borne, on account of the exceedingly deranged state of the system. Forty, fifty, or sixty drops of laudanum are frequently not more than sufficient to relieve the fit. I once had an extraordinary case of this kind, where such a dose was given without any effect. A drachm was then given, but still without any effect, and so also were two drachms. Seeing this to be the case, the medical gentleman who was attending the patient grew out of patience, and gave half an ounce; by means of which he merely got rid of the paroxysm. When the next paroxysm came on, however, that dose failed entirely, and six drachms were given, which produced tolerable relief, but

not enough; and at last many drachms were given for a dose, with no more effect than that of putting a stop to the paroxysm. These are states of the system in which ordinary doses are of no use; but, in general, from forty to sixty drops are borne very well, and are sufficient. It is useful to combine the laudanum, in these cases, with a dose of ether; and if you mix them up with ammonia, or with musk, or assafoetida, you will generally add to their good effect. But opium generally answers the purpose. Should, however, the patient be plethoric, and have chronic bronchitis and fulness of the chest, it would be very wrong to give a large dose of this description, lest it should produce apoplexy; and it would be right to take away a certain quantity of blood. Some patients are relieved by cupping, and some by dry cupping.

After the Paroxysm.—When the paroxysm is over, it would be useful to endeavour to prevent its return by giving a dose of one of the preparations of opium together with ether, but in a smaller quantity than in the former case. Some persons have told me that they have seen very great relief from cantharides in this complaint and in hooping-cough, but whether they really are beneficial I cannot tell: the use, however, of opium, ether, musk, and assafoetida, is unquestionable. Some have found very great relief from smoking stramonium: I have seen many persons who have derived benefit from smoking the leaves and stalks of stramonium chopped up together. Some have found the smoke of tobacco serviceable, but far fewer than have found benefit from stramonium.

You will find it of very great use to make patients drink strong coffee, without milk and sugar: it is an old remedy, but a very good one. There ought to be no grounds in it, because they may disturb the stomach; and that organ, in this complaint, is generally much disposed to indigestion. If it should so happen that a paroxysm comes on from a hearty meal, a good emetic either of mustard or sulphate of zinc—something which will not nauseate the patient long, but empty the stomach as quickly as possible—will be found very serviceable.

I am supposing all along that the patient is free from chronic bronchitis—has simple pure asthma. If, however, there be any chronic bronchitis present, you will find squills, digitalis, colchicum, and ipecacuanha, will all be useful; some by increasing the flow of urine, and others by increasing the secretion from the air passages. Some have found relief from opium and prussic acid, and others from hyocyamus and conium; but, I think, if you

want an immediate effect, there is nothing equal to opium and stramonium. But there is no rule for these things; some persons are relieved by one article and some by another. It is right to consider this as a spasmodic disease which may be removed, and if it can it should. It may arise from a full stomach, and then an emetic is the best remedy; it may arise from grass, and then the chlorides scattered about the room, I conceive, would be the best thing: but if you cannot remove the exciting cause immediately, or not at all, then you will find that the best mode will be a good venesection and opium.

Prophylactica.—In regard to the prevention of the disease, besides giving the same things, and besides removing the patient from the exciting cause if it be known, it is of great use to pay attention to the stomach and bowels. Every body knows, that if the abdomen be distended, the diaphragm cannot descend freely, and we can scarcely breathe; and asthmatic people suffer under these circumstances to a very great degree. Dr. Wilson Philip has spoken highly of galvanism in this complaint, and no doubt it does good; but you cannot expect it to be universally efficacious, when you consider that it is often united with organic affections and chronic bronchitis. When persons are very weak, you find that tonics are necessary, particularly iron. Dr. Bree used to exhibit the carbonate of iron particularly in the disease; but I have not found it useful, except as a tonic. In regard to the inhalation of chlorine, it may be had recourse to in every form of asthma. You may impregnate water with it, and make the patient breathe through it, and in that way inhale it. If you think proper, you may adopt the same means with regard to prussic acid and conium. Some have found benefit from tar, and others from tanners' liquid, put in one corner of the room. Another way of giving persons the advantage of these things is to impregnate water with them, and make patients breathe through it three or four times a day.

ON THE STRUCTURE OF THE OS INCUS.

By HENRY JONES SHRAPNELL,

Surgeon to the Royal South Gloucester Regiment of Light Infantry Militia, Member of the Royal College of Surgeons, and Fellow of the Geological Society of London.

THE following observations on the structure of the os incus are offered with the

view of deciding a point in anatomy, upon which, at present, there appears to be a considerable degree of doubt—namely, whether the *os lenticulare vel orbiculare*, the smallest of the ossicula auditus, is entitled to be considered as a separate bone, or merely as a process of the *os incus*?

The most generally received opinion appears to be that it is a separate bone; and it has been accordingly so represented, not only in our best plates, but in the preparations put up in anatomical museums. If it is a separate bone, it must have two articular surfaces—one connecting it to the *incus*, the other with the *stapes*. The surface by which it is articulated with the head of the *os stapes*, may very readily be perceived: it forms an oval convex ball, the long axis of which is about a third of a line in length. Minute as this dimension is, the joint presents the usual shining surface, and has edges to which its capsular ligament is attached, and which may be seen, both to the *processus lenticularis* and the corresponding concave depression in the head of the *stapes*; together forming an enarthrodial or ball and socket articulation. Now it may readily be conceived, that, to an eye accustomed to the inspection of minute objects, and assisted by a good magnifying power, an articular surface would be as apparent on the side next to the *incus* as it is on the part next to the *stapes*.

Cloquet has described the *os lenticulare* as having two convex articular surfaces. In order to expose these surfaces, so as to obtain a perfect view of them, I subjected four temporal bones to a full process of maceration, that all ligamentous connexions might be destroyed, and the bones separated without violence. But in each of these instances, and in numerous temporal bones of various animals, no separation of the *lenticulare* from the *incus* could be effected by maceration. The same circumstance may be observed in those *ossa incudes* which may occasionally be obtained from temporal bones that have been long buried, and in which a more complete process of decomposition has taken place than can usually be obtained by maceration. The appearance of the connexion of the reputed *os lenticulare* to the *incus*, is that of a distinct neck or process of bone, which is given off at a

right angle from the inner side, but not quite from the extremity of the long crus of the *incus*. This process thus spreads out into an oval plate, which forms the articulation with the head of the *stapes*.

The oval plate has an oblique direction across the crus of the *incus*, the anterior being lower than the posterior part; and in like manner the process, or neck of bone supporting it, arises in a slanting direction, and is thicker and stronger at its posterior than at its anterior portion. This neck of attachment appears also to be somewhat convex inferiorly, and concave superiorly; hence there is a larger space between the oval plate and the crus of the *incus*, above (and particularly at the anterior part) than below, or on the inferior side of the process of attachment: from which conformation the neck of the process has a twisted appearance.

It has been suggested that the osseous union between the *lenticulare* and the *incus* might be occasioned by a process of disease, causing an ankylosis of the joint. This, however, is scarcely possible, as it occurs so constantly, and in very young animals, without the slightest evidence of any disease having existed. Indeed, a process of inflammation capable of producing the bony union of any natural joint, existing between the *os lenticulare* and the *incus*, would in all probability, in some instances at least, produce a similar effect between this bone and the head of the *stapes*. An ankylosis, it may also be observed, is a result of long-continued disease within a joint, and seldom, if ever, occurs free from some irregularity produced in the natural parietes of the joint itself; and by which a diseased state may readily be detected.

The constant occurrence, therefore, of this ossific union in very young animals, free from all diseased appearances, places the possibility of an ankylosis entirely out of the question.

It follows, in consequence, that the *os lenticulare* is to be struck out of the list of the bones, and should be considered merely as a process—namely, the *processus lenticularis* of the *os incus*. The *os stapes*, and not the *os lenticulare*, is the smallest bone in the body. The number of the ossicula auditus is three, not four, to each ear; and the total num-

ber of human bones is two hundred and forty-seven*.

MEMOIR ON ŒSOPHAGOTOMY†.

By M. L. J. BEGIN,

Surgeon-major to the Military Hospital of Instruction at the Val-de-Grâce.

AMONG the various mechanical lesions of our organs, there are few more severe, or more difficult to manage, or which may place the surgeon in a more embarrassing and painful situation, than

* The total number of human bones has been variously computed by different anatomists: some have not included the teeth, or the bones of the ear; others consider the os coccygis as a single bone, and others, again, have not admitted ossa sesamoidea. In the above computation, the teeth have been included, the os coccygis has been reckoned as three pieces (for although it varies from two to five, three appears to be its most constant number), and four ossa sesamoidea have been counted to the hands as well as to the feet.

† Abridged from the *Journal Univ. et Hebdomadaire*.

the presence of foreign bodies fixed in the pharynx and œsophagus. The anxiety, the suffering, the alarm of the patient; the uncertainty which often attends the exploration of the particular parts affected; and then the necessity of acting with the utmost promptitude, in order to avoid the rapidly fatal consequences which may ensue,—all these circumstances render the result highly hazardous, even in the hands of the dexterous practitioner.

When a foreign body has become fixed in a part of the œsophagus or pharynx, where it may be felt either with the fingers or by the aid of instruments, and that it can be seized there, and drawn up with forceps, or pushed down with the probang, the indication is clear, and surgery presents a great number of expedients and clever methods of which we may avail ourselves. But when the body resists all our attempts to remove it, and remains obstinately fixed, the case is very different, and calls for the application of extraordinary means.

Precepts of a contradictory kind, touching those means, have been offered by men of eminence. When the foreign body is fixed in the cervical region of the œsophagus, and is perceived projecting, and protruding the integuments of the neck, it is generally recommended to cut down on it. The operation is simple and easily practised under such circumstances. In the *Memoirs of the Royal Academy of Surgery*, a case is related by Honde of a woman who fell upon a spindle which she held in her hand; its long extremity penetrated the pharynx, and broke there. The patient suffered much, respired with difficulty, and could only express herself by signs. An attentive examination of the throat was made, but nothing could be discovered, when at length Honde detected beneath the skin, near the transverse apophysis of the fifth cervical vertebra, a projection formed by the extremity of the spindle; this he exposed, seized, and drew out, without any difficulty. The cure was most complete. Needles, pins, fish-bones, and sharp fragments of bone of various kinds, have also made their way through the œsophagus, and being detected in the skin, have been extracted by simple incision.

It is otherwise, however, with foreign bodies which are round or obtuse, distending the walls of the passage so as

to be felt from without by the fingers,—though this latter peculiarity is rare. A case of the kind is recorded in the work above quoted. In the year 1738, Goursauld was called upon to relieve a man who had swallowed a bone about an inch in length, and six lines in breadth, and which could neither be drawn up, nor pushed down into the stomach; he accordingly determined to make an incision on the place where the bone was, and he succeeded perfectly in withdrawing it. With the help of a simple bandage the cure was fully effected. A similar operation was performed by Roland, surgeon-major of Mailly's regiment.

But notwithstanding those and such like cases, it seems to have been unanimously agreed upon by more recent authorities, that when a foreign body is fixed in the œsophagus, without making any projection that can be felt through the tissues, we should temporize and simply meet the symptoms which are most pressing, causing the patient to observe a severe regimen, nourishing him by the assistance of lavements, and, in short, waiting patiently for the efforts of nature to disturb and remove the foreign body. Such is the doctrine professed by the Desaults, the Boyers, the Delpeches, and some of the latest writers on operative medicine; and examples of the fortunate results derived from such a method of treatment, are to be found in various journals, and particularly among the memoirs of various societies.

In the great majority, of cases it seems generally admitted that foreign bodies become fixed about the commencement of the œsophagus, or at most not deeper than the superior border of the sternum. When a substance passes the latter limit, it almost always descends lower, by reason of the gradual contractions of the gullet, the dilatation of which is besides neither prevented by the bulk of the trachea, nor by the osseous ring at the summit of the chest. That part of the œsophagus which is embraced by the diaphragm may possibly form another strait, which certain bodies cannot pass, and above which they may become lodged for a greater or less space of time. In many cases an inward sense of pain will point out the track of the body along the dorsal column; this pain is aggravated at the moment of passing the cardia, after

which a distinct feeling of relief announces that the danger is over, and that the substance has entered the stomach.

But it is by no means difficult to shew that, in the greater number of cases, wherein, as I have said, the foreign body has become fixed at the upper part of the œsophagus, the efforts of nature, so far from relieving the patient, are in general but too often attended with fatal consequences. Felix Plater reports the case of a child who had swallowed some fish bones, which became imbedded in the walls of the œsophagus, whence there resulted such violent inflammation that death with suffocation ensued. Fabricius Hildanus relates the case of a young man who died on the ninth day after having had a small bone impacted in the œsophagus. Death resulted in this case partly from the inflammation produced by the presence of the foreign body, and partly from the vain but reiterated attempts that had been made to remove it.

The following case, recorded by Guattani, will further illustrate the point in question. A man about 40 years of age threw up into the air a roasted chesnut, and as he held his mouth open to catch it, it entered and became fixed in the œsophagus. He was sent in the course of a few hours to the Hospital of the Holy Ghost, at Rome, in which Guattani practised. Upon examining and questioning the man, a doubt was raised as to the real state of the case, partly because the man was drunk, and partly because he felt no difficulty in breathing, spoke easily, and had even vomited; besides, no tumor was felt outwardly; yet, as he evinced a sensation of pain upon compressing the larynx, especially on the left side, it was suspected that the chesnut might possibly be fixed in the passage. The usual remedies in such cases were tried; but much difficulty was experienced in making use of the bougie and other similar instruments, chiefly because the lower jaw was affected with spasm. The countenance of the patient was greatly swollen; the tongue was moderately moist; the pulse frequent. He complained of a burning heat inwardly, and appeared to be somewhat delirious. As he could not swallow food, several nourishing lavements were given him; there was nothing but iced water with which he could

manage to slake his thirst. On the sixth day, notwithstanding the frequent bleedings which had been practised on him, he had a considerable hæmorrhage from the nose. On the eighth the respiration was impaired, and there was debility and cough. On the tenth he was greatly sunk; yet in this wretched condition he survived till the nineteenth day, when he perished, apparently from pure exhaustion. The chest was found entire upon opening the larynx after death; its convexity was turned forward, and its pointed end was fixed in the wall of the left side of the passage. The œsophagus itself was greatly contracted both above and below the foreign body. The walls of the œsophagus and those of the trachea had contracted strong adhesions; they were sphacelated at the place that had been pressed upon, and a small hole, about the size of a pea, had been made through the mortified part, opening a communication between the two organs.

Here was a body moderately voluminous, rounded, yielding, allowing the patient to breathe, to speak, even to swallow water and soup—presenting, in short, as it would seem, the most favourable conditions for removal; yet there it remained where it first became fixed, until it produced the consequences which we have seen. So much for the result of waiting upon nature!

But it is not merely accidents which determine inflammation that may put the life of the patient in jeopardy, and ultimately cause his death: the following case will shew a further variety in the circumstances. A soldier, while eating his soup, swallowed a piece of bone, which stuck in the œsophagus. Attempts to push it on towards the stomach were made, and seemed to be successful. Soft and liquid food could now be taken without difficulty, and a probang, upon being introduced, readily reached the stomach. The patient seemed to labour under no further inconvenience. He left the hospital, but in the course of a month he returned again, complaining of a sharp pain in the left side of his neck. By the employment of antiphlogistics his ailment was removed, and he left the hospital once more. The pain, however, which never entirely left him, except for short intervals, became again severe; the patient returned for the third time to the hospital—not, indeed, for the par-

ticular accident in question, but for a gonorrhœa which he had contracted. Every thing seemed to be going on well, when he suddenly threw up large quantities of blood, perhaps to the amount of seven pounds. The hæmorrhage presently ceased, but the next day it returned, and proved fatal. On examining the body, there were found in the œsophagus, about its upper third part, two parallel ulcerations; that on the right side nine lines in breadth, and that on the left twelve. Opposite the latter there was an adhesion between the œsophagus and the corresponding part of the carotid. In this vessel, moreover, erosion had produced a small opening, about a line in diameter, which proved to be the source of the hæmorrhage.

I might cite several other cases similar to the preceding: I shall, however, confine myself to one, which has been communicated to me by M. Bernast, of the Toulon hospital. A young soldier thought he felt, while eating soup, that he had swallowed a sharp bone, or a pin; consequent to which he experienced a pungent, lancinating, and occasionally insupportable pain. On entering the hospital he was treated with antiphlogistics, but without success: the pain increased, and kept the unfortunate patient in restless misery. Nausea at length supervened, and he threw up some ounces of blood. Eventually he was seized with convulsions, and died on the eighth day. On opening the body, a large quantity of blood was found in the chest, especially on the right side. The heart and aorta were sound, but on turning aside the pulmonary artery there was found in front of the œsophagus a flatted, sharp pointed bone, indented on one of its edges, and resembling one of the bones of the nose. This had produced an opening in the œsophagus, and a corresponding, though very minute one, in the pulmonary artery, at the spot where this vessel divides in order to be distributed to the lungs. The point of the bone was still seen in actual contact with the lesion.

Thus, then, we find that bodies may become fixed in the œsophagus, and though they may not very sensibly affect either the deglutition, the respiration, or the voice, may yet produce fatal injury of the carotid, aorta, or the pulmonary artery. Sometimes, too, the

hinder part of the trachea may be perforated, and death ensue in consequence of the unnatural communication thus opened: and Baron Larrey tells us of a man who died from the effects of a five-franc piece which was detained in the lower part of the œsophagus.

From what has been said, it may be perceived that fatal consequences may ensue even when the symptoms of the presence of a foreign body in the œsophagus may be very evanescent.

Now my impression is, that in such cases we should operate, maugre the precepts of distinguished authorities to the contrary. An operation will add hardly any thing to the severity of the case; and while it by no means puts life in additional danger, it may be the only means of saving those who, left to the unaided efforts of nature, would be sure to die.

Most of those who have proposed to operate on the œsophagus—such as Guattani, Chopart and Desault, and Vacca—have been more theoretical than practical. None of them seem to have had a proper idea of œsophagotomy, as it ought to be performed on the living body.

When the substance in the œsophagus makes no projection in the cervical region, the surgeon will have no other guide in operating than his anatomical knowledge; and if he cannot trust to this, better he abandon the task altogether.

I shall now proceed to point out a mode of operation which I conceive to be more simple, easy, and sure, than any other hitherto employed. But perhaps it may be better previously to relate the cases in which I had occasion to put it in practice.

CASE I.—Piece of bone fixed in the Œsophagus—Various attempts to remove it—Operation—Cure.

B., a soldier of the first regiment of the line, while eating soup, doubtless with over haste, on the 4th January, 1832, swallowed a fragment of a beef bone, which presently became fixed in his œsophagus. Restless and anxious, he presented himself immediately to the surgeon-major of his regiment, who made some attempts to extract the bone, but without success. Next day he went to the hospital Maison-blanche, where fresh but equally fruitless attempts were made. On the 7th he was taken into one of the clinical wards of the Val-de-

Grâce, where, by the first trials, a change in the position of the bony fragment was effected, and the patient was somewhat relieved; but the amelioration was slight and transitory. On the following day I saw the man for the first time; he was 24 years of age, of a good constitution, and in his *morale*, mild, patient, resigned. The account he gives of his sensations is clear. The impediment which he feels in deglutition, and which is constant, is accompanied by tension of the neck, embarrassment in his breathing, and sometimes with danger of suffocation. The cervical region is largely swollen, particularly on the left side. The mouth can only be opened imperfectly, which renders all our manœuvres of exploration laborious and painful. The patient cannot throw back his head, so that in attempting to penetrate the œsophagus our instruments are bent and driven against the upper incisor teeth, whilst these latter are scarcely separated from the lower incisors enough to admit the forefinger between them. Yet by the aid of a gum elastic sound, at the depth of seven or eight inches there is felt a foreign body, hard and bulky, impacted in its place, and that place apparently below the cricoid cartilage, and about the upper portion of the trachea. The large curved œsophagus forceps cannot reach it, or if they can, cannot grasp it with any force. On introducing the probang of Willis, the body is readily touched; but it is found to be too firmly fixed, and gives excessive pain to the patient, when an attempt is made to push it down to the stomach. All this time the respiration is greatly disturbed, an abundant secretion of saliva and mucus is given out, and we are obliged to refrain from further trials.

Twenty leeches were applied to the neck; low diet; tisane of gum potion. Deglutition difficult; an oil draught could not be taken. Twenty leeches more, same evening, in order to relieve a painful local excitement. That night the patient had the house-surgeon called up, and assured him that the bone had ascended; but this upon examination proved to be wholly imaginary.

The patient was better next morning; the swelling diminished; respiration decidedly easier; but the voice is peculiarly modified, no doubt by the pressure of the foreign body on the trachea. The head, however, cannot yet be

thrown back, nor the mouth sufficiently opened. It is determined to irritate the parts no longer for the present, by the introduction of instruments. Antiphlogistic treatment continued, with a view to reduce the swelling still further, and if possible to facilitate the loosening of the foreign body, previous to fresh attempts at its removal. But all this appeared illusory, when in the evening the swelling began again to increase, and the tonsils augmented in bulk to such a degree as to leave only a narrow passage for the atmospheric air. Restlessness, yet some sleep at last.

The mouth opened somewhat better on the following day, and there was every appearance of suppuration having set in. An emetic was administered, which enabled the patient to throw up some bilious, mucous, and puriform matter.

The four or five following days passed over without any marked change in the symptoms. On the 15th the patient was submitted to a careful and special examination. The odour of suppuration was strong from the mouth, and as if gangrene were approaching. Twelve days had now elapsed without any thing having been gained by waiting en nature, and without any prospect of amelioration in case the same course should be continued. No doubt by waiting longer the body might make its way out, but it might be at the expense of an erosion either of the air passages, or of some great vessel, such as the aorta, the carotid, or the pulmonary artery, and the patient thus suddenly perish. Œsophagotomy, then, was the only resource; and this after much deliberation was deemed most advisable. The patient was still in a condition not to be despaired of; and the place of the foreign body was pretty exactly guessed at from the following signs:—1. The patient's feelings, and his assertion as to the spot where the impediment was. 2. The change of voice which had occurred, and which indicated that the pressure was on the upper part of the trachea. 3. On putting the patient's chin on the middle of his sternum, it was evident that the trachea was displaced upwards and obliquely to the right, and that the thyroid cartilage was turned nearly half an inch over on that side. 4. And lastly, there was a flattening of the left anterior region, caused partly by the removal of the trachea to

the right, and partly by the displacement of the vessels to the left. On the whole, we had reason to presume, that, on a division of the soft superficial parts, the finger introduced into the wound would obtain ample indication of the exact place of the foreign body. I accordingly proceeded to operate as follows:—

Operation.—The patient was left in bed, his head resting on pillows, and kept steady by an assistant; his face was slightly turned to the right, and the neck gently extended. A good light was procured by removing the bed commodiously to one of the windows. An incision was now made through the integuments, parallel to the trachea, and extending from nearly the left sterno-clavicular articulation to beyond the superior margin of the thyroid cartilage, along the furrow that separates the sterno-cleido-mastoid muscle from the trachea. The omo-hyoid muscle was then divided. All this time an assistant was gently drawing the trachea to the right, while the operator, with the fingers of his left hand, was guarding the primitive carotid, the internal jugular, and the nervous trunks of the great sympathetic and pneumogastric. A branch of the superior thyroid artery was divided, and immediately secured with a ligature. In about a moment after, a little drop of pus was seen on the bistoury, and its source was presently discovered. It was the œsophagus itself which was opened, and from whence there issued a great quantity of ill-coloured pus, intermingled with flocculi of cellular substance. An attempt was now made to find the foreign body, but the finger could not reach it, and the opening had to be enlarged. The trunk of an artery, most probably the superior thyroid, was accidentally wounded in this part of the operation, and was secured with some difficulty by a *mediate* ligature effected with a needle.

The foreign body was at length felt; it was situated in a part of the œsophagus corresponding with the middle of the first piece of the sternum. Several instruments, both straight and curved, were now applied; they could seize it, but seizing along with it the wall of the œsophagus, they could not draw it out. After several fruitless attempts, its situation was shifted a little nearer to the opening; and then by applying beneath it a tenaculum, using at the same

time the left fore-finger as a guide, the bone was fortunately extracted.

Five and twenty minutes were consumed in the operation, the greater part of which time was spent in getting the foreign body out. The patient suffered but little, and lost scarcely two ounces of blood. He was dressed with cerate and charpie, compresses, and a circular bandage.

The bone was flattish, irregularly quadrilateral, sixteen lines in length, fourteen in breadth, its edges abrupt, and bearing very acute angles (fig. 2.)

The patient was kept perfectly abstinent after the operation; the only thing allowed him was a morsel of orange to suck. He had a little sleep in the night. The next day, by means of an œsophagus tube, a *bouillon*, with the yoke of an egg, was introduced into the stomach; and the same method of nourishment was practised for several days after. Yet the patient gathered strength very slowly. On the sixth day he fainted while the dressing was changed. Some sulphate of quinine was added to his ingesta; and rice cream was substituted after a time for *bouillon*. At length the food reached the stomach without the aid of the tube; the wound closed; and about the 20th of the following month its cicatrization was complete. There is no detriment whatever affecting the deglutition at present, and the patient now performs some of his military duties once more.

By that sort of chance with which the surgeons of hospitals are pretty familiar, namely, when one extraordinary case occurs, a number of them frequently following, while perhaps months and years may again elapse without any similar occurrence, B. was scarcely convalescent, when another soldier presented himself at the Val-de-Grâce, labouring under a perfectly similar complaint.

CASE II.—*Alarming effects of a piece of Bone fixed in the Œsophagus—Operation—Perfect recovery.*

R., 28 years of age, of rather a delicate constitution, swallowed a piece of bone on the 13th of February. Four grains of tartar emetic were given him immediately; but the efforts of the vomiting did not expel the foreign substance. Next day he came into the hospital. There were no remarkable

external local symptoms, nor was the voice affected. Several fruitless attempts to extract, and afterwards to push down the body, were made. Bleeding was not thought necessary, as it did not seem indicated. On the fourth day a special examination was made, and by means of a gum elastic sound the foreign body was recognized about the lower part of the neck; it was solid, voluminous, and nearly filling the passage. Various, and some of them violent, experiments were made with different instruments to try to effect a dislodgement, but all in vain. The case seemed to be hopeless unless an operation were tried; this, therefore was agreed upon, and it was performed on the eighth day after the accident. M. le Baron Larrey, and most of the professors and other officers of the Val-de-Grâce, were present on the occasion.

Operation.—By a longitudinal incision, similar to that practised in the preceding case, the integuments were divided parallel to the left border of the trachea and larynx. The same precautions also were used in guarding the nerves and vessels. Upon reaching the œsophagus, the indicator of the right hand was employed to trace out the foreign body, which was found situate a little below the level of the upper border of the sternum, too low to be cut down upon without danger of opening the trunk, or some of the principal branches, of the inferior thyroid artery. The œsophagus was therefore opened above it, and with the aid of strong forceps and continued exertion, the foreign body was at length detached and taken out. The patient scarcely lost two spoonsful of blood, and suffered very little pain.

The foreign body proved to be a piece of the spongy part of a long bone. It was conical in shape, with its larger extremity rounded, and the smaller one very sharp, abrupt, and formed of the solid part of the bone. This sharp end it was that had penetrated the wall of the œsophagus, and constituted the greatest obstacle to its removal. It measured altogether eleven lines across the base, and sixteen from the summit to the base (fig. 3.)

Simple dressings, and the same after-treatment as in the former case. On the sixth day a *bouillon* was given; and to quiet the febrile accessions which

disturbed the patient every evening, a lavement, containing three grains of sulphate of quinine in six ounces of water, was exhibited. This had the desired effect. The convalescence proceeded favourably, and by the 9th of April the man was able to leave the hospital perfectly cured, and is now engaged in some employment about one of the theatres in Paris.

It will sometimes happen that the foreign body is fixed more deeply in the œsophagus than in either of the preceding cases, and that there is no chance of cutting down on it; even in this case œsophagotomy will enable us to give the patient his only chance of life. If such a proceeding had been adopted in the following instance, which was very recently communicated to me, the result might have been very different.

CASE III.—Bone in the Œsophagus—Hæmoptysis—Death.

D., a soldier of the 4th lancers, swallowed with his soup a large, irregular, flattish piece of bone. He imprudently used every effort to swallow it down completely, but it stopped below the pharynx. There it produced the most painful and convulsive action of the pharyngeal muscles, until one of the military surgeons, after attempting in vain to extract it, pushed it down deeply into the gullet with a probang.

It was thought, even by the patient himself, that it had gone down all the way. For several days D. took nothing but soup, complaining grievously of sharp pain in that part of the œsophagus which lies behind the bifurcation of the bronchia, evidently arising from the rubbing of the bone against the parietes of the passage. He was obliged to enter the hospital at last, and was there treated as a fever patient labouring under acute pneumonia. Local and general bleeding, low diet, &c. Patient better; only complaining of a dull pain in the spot already mentioned. He could take some light food, which he even relished. All of a sudden the primitive symptoms recurred, and a violent hæmoptysis took place. Every method was tried to abate the latter disorder, but in vain; the patient died on the eighth day, bloodless and exhausted.

On examination of the body after death, the lungs were found in a state

of inflammation; but the state of the œsophagus was the principal object of the inspection. In that part of the gullet which corresponds with the fourth dorsal vertebra, the foreign body was found. Two of its opposite angles had passed clean through the parietes of the œsophagus, even to the extent of seven or eight lines (figs. 4 and 5). The inflammation in the posterior lobes of the lungs could be traced to these sharp projections.

Facts like the foregoing would no doubt be much more numerous in the records of science, did but practitioners possess as much eagerness for communicating their unsuccessful as their successful histories. Until, however, this is the case, the respective value of doctrines, methods, and processes, can never be fairly ascertained.

Practical Remarks.

In operating, it may be observed, that the left will be found the more convenient side for proceeding to work; for the œsophagus, in descending towards the chest, deviates gradually, and emerges on the left, in order to gain the side corresponding with the aortic curvature. I do not mean to say, however, that this deviation is to such an extent as to render operating from the right side impossible, or even much more difficult than the left.

The extent of the first incision must be limited below to within one or two fingers breadth of the sternum, in order to avoid the inferior thyroid artery. Above, it should not pass beyond the digastric and stylohyoid muscles, partly to avoid needlessly cutting into the pharynx, but more particularly to escape wounding the superior laryngeal nerve, as well as the lingual and facial arteries, or at least their principal branches. As to the superior thyroid artery, its incision is neither very important nor dangerous (fig. 1.)

The most convenient place for the surgeon, in operating, is on the left side of the patient. His right hand, towards the patient's head, is thus most favourably situated for all the requisite purposes. The assistant, who is placed on the opposite side, must be a person on whose intelligent co-operation he can reckon. As to the mode of seizing and extracting the foreign body when the

œsophagus has been opened, this is a point on which no certain rule can be laid down. Success in this part of the operation will greatly depend upon the tact, dexterity, and presence of mind of the operator. The strong, curved, polypus forceps, will perhaps be found the most convenient instrument to use; and there should be a supply of these instruments, in all their variety, at hand.

After extraction, the parts of the wound should not be united by sticking plaister or sutures, but merely brought together and covered with a perforated cloth laid over with cerate or styrax, and over that a quantity of downy charpie. Local and circular compresses, surmounted by some turns of a roller, will complete the *appareil*. The rationale of such a method of dressing simply lies in the fact of the existing inflammation of the tissues that had enveloped the foreign body: these may most probably be even suppurating and gangrenous; besides, the parts must have undergone much irritation during the process of operating; and above all, there is much morbid or dead matter to be discharged, before a healthy cicatrix can be formed. It may be observed, however, that the wound is in general not slow in closing, even about the part diseased; for in general between the sixth and twelfth day after the operation, the use of the sound will be superfluous in administering food.

In conclusion, œsophagotomy, as I have practised it in the Val-de-Grâce, and described it in this paper, will still no doubt remain a serious and delicate operation; but with care, and some practice on the dead body, there is no surgeon who may not reasonably attempt it with good hope of success. It is certainly not a more difficult operation than ligature of the femoral artery, or of the end of the axillary. One cannot easily account for the dread which practitioners have constantly betrayed of adopting it, even where its adoption could scarcely fail to be productive of good. If what has been here said shall in any manner serve to inspire confidence; if the examples cited in this memoir shall find imitators; and if some unfortunate persons, whose doom were otherwise sealed, be hereafter snatched from death—the object which I proposed to myself in the foregoing pages, will have been abundantly answered.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

The Analysis of Inorganic Bodies. By J. J. BERZELIUS. Translated by G. O. REES.

WE have here a little work which will be found to be a valuable acquisition to the student of practical chemistry. It contains the pith and substance of the precepts laid down by the great master of analysis in his voluminous Elements; at the same time that every process described in it is stated with a clearness which must satisfy every inquirer. The arrangement is simple and commodious. After some general remarks on the analysis of solid substances of the inorganic class, the author proceeds to give an account of the methods which he employs in qualitative and quantitative analysis; and then he states his rules for analysing the gases, mineral waters, and a large variety of the salts. The interests of the pupil are constantly kept in view; and we cannot but admire the occasional occurrence of hints like the following in the pages before us:—

“Persons who know little of chemistry ought to exercise themselves principally in quantitative analysis, persuaded that without being acquainted with its branches, they are quite incapable of all scientific research. It is necessary to be accustomed to weigh with the nicest exactitude, to pour out liquids without loss, so that the last drop does not run on the outer side of the vessel: it is necessary to keep an account of a variety of trifling things, the neglecting of which will render useless a troublesome process of many weeks.”

Such is the sort of easy manner in which the genius and experience of Berzelius can condescend to instruct even the very humblest class of learners! In the present version we find, in addition to the article Analysis, which specially belongs to the 12th volume of the Elementary chemistry, that much information is extracted from other volumes of the same work, in order to render the manual as complete as possible. Under the head of the arsenites, for example,

we have in a note the author's process for detecting arsenious acid in cases of poisoning, and the translator appends to this the methods of Rose, and of Christison, which leave nothing to be desired.

To all who possess the excellent treatise on the Blowpipe, by the same illustrious author, the present tract, we doubt not, will be found very acceptable as a companion, affording a body of illustration suited to render the former in every way more efficient and practical.

Illustrations of the Mechanism of Parturition. BY CHARLES E. ROSS, M.B. &c.

THIS is a fasciculus of half a dozen lithograph prints, representing the pelvis in its various aspects; the head of the fœtus, with its several diameters, and the position of the parts in natural labour. To the student of midwifery it must prove highly useful, while its cheapness gives it a claim to extensive circulation.

MEDICAL GAZETTE.

Saturday, May 11, 1833.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

CONTEMPLATED CHANGE IN THE APOTHECARIES' ACT.

WE mentioned last week that a bill had been actually prepared, and was lying at the Home Office ready to be brought into parliament, the object of which was to grant to the graduates of the Scotch Universities, and to the diplomatis of the Edinburgh College of Surgeons, the privilege of practising in England as apothecaries.

The proposed measure would seem, at first sight, to be a very simple one—a mere extension of the present Apothecaries' Act. But even supposing it were nothing more, would it not be as well, before adopting a change which *may*

be attended with important consequences, to consider what has been the working of the existing system regarding general practitioners; whether the public be better served or worse than they were anterior to 1815; whether the medical profession is on a more steady and respectable footing than it previously was; whether, in short, upon the whole, good or evil has resulted from the exercise of the powers confided to the gentlemen at Blackfriars?

We presume it will be admitted by all that some test of education and knowledge is requisite before persons are allowed to practise so difficult an art as ours—to act as a barrier between the public and the plunder of ignorant and unprincipled men. But we have always held, and still do hold, that the task of licensing those who should be found qualified to practice medicine ought not to have been placed in the hands of the worshipful Society of Apothecaries; that this ought to be the proper and peculiar province of the College of Physicians; and it is our firm persuasion that had not the latter, in culpable supineness, or doting ignorance of the progress of opinion, neglected the opportunity which was offered them of controuling this department of medical polity, they would have enjoyed a very different rank in public estimation from that which they at present occupy. That, however, is their own affair; and besides it is now past; "time and the hour" which might have served their purpose are irrevocably gone, and can never be recalled. But this opinion as to the parties in whose hands the regulation of medical practice in England ought to have been placed, has no effect in making us regard with a jaundiced eye the acts of those who—most unexpectedly for themselves—were called upon to exercise highly-important and responsible duties.

A deliberate consideration of the

measures adopted by the Society of Apothecaries induces us to award to them the praise, which we think their due, for their zealous, honest, and judicious efforts to improve the education, enhance the respectability, and elevate the rank of that department of the profession intrusted to their care; and for thus adopting obviously the best mode of carrying into effect the purposes of the Act. In these respects we do not think that justice is usually done them; they, to be sure, only enjoy the enviable distinction that attaches to every ruling body in this country—that of being unpopular. It is the hereditary and unquestionable right of Englishmen to condemn the powers that be—be they who they may; and it is quite proper that the Society of Apothecaries should constitute no exception to the general rule. Granted then—they have many enemies—and that even they who are not hostile to them think they may have been occasionally somewhat too busy and pragmatismal; let not this, however, induce us to shut our eyes against their fair and strong claims to commendation: above all, let it not lead us to heap upon them such opprobrious epithets as we regret to see are made use of in some of the petitions of the Scotch graduates who think themselves injured by their regulations. Nor can we omit this opportunity of casting back with disgust upon their worthless authors those still more injurious accusations with which some of our contemporaries fill their pages. We are told by those who think it no shame to live by the slander of their brethren, that the Society of Apothecaries have netted 40,000*l.* by the act. A statement such as this may suit the grade of intellect possessed by the rabble politicians who surround the hustings at our popular elections, and settle all disputed points by the yelling of their most sweet voices, aided by plentiful discharges of mud and brick-

bats;—but that assertions absolutely false, and hyperbolically absurd, should be addressed to a profession of intelligent men, is as gross an insult as can well be offered them. Now the author of the statement in question must have known that it was untrue; because it is but a few years ago that Mr. Hume, *acting upon false information*, moved, in the House of Commons, for returus setting forth the receipts and expenditure under the Apothecaries' Act; and from these it appeared that the income did not more than suffice, and was actually spent in carrying into effect the legitimate objects of the Bill, and that none of the Court of Examiners received a sum exceeding 100*l.* per annum for their very laborious and responsible duties. These papers were printed at the time, and proved so satisfactory (perhaps we should rather say so *unsatisfactory*) that the honourable economist could suggest no retrenchment: and if *he* could not, it will probably be conceded that it would be difficult to find any other with nerve enough to do so.

But to return. That good has resulted from the act of 1815, appears to us to be undeniable: the public have been supplied with a better educated race of men than before, and the profession has been proportionally raised in respectability. Still no doubt it remains to be ascertained whether these objects may not equally, or more efficiently, be accomplished in some other manner, and whether there be not evils resulting from the present system which counterbalance its advantages. It is a gross absurdity, evidently, that no man be licensed to practise in England who has not served a five years' apprenticeship; and any change which should get rid of this arrangement we would hail with pleasure: but at the same time it is only fair to add, that this is a condition which was stupidly appended to the bill in the House of Lords, and with which the

Apothecaries had nothing to do. That the act has injured the Scotch medical schools—or rather that its repeal would greatly benefit them by sending to their lecture-rooms a new class of students, called into existence by the “Worshipful Society,”—is apparent; as it is no less obvious that it would be detrimental, nay ruinous, to the English provincial schools, which have been established under the regulations of the present Court of Examiners. Still, if it can be shewn that the public would be gainers by the proposed change, and that evil has accrued from the Act, of course the effect upon the medical schools would be a matter of no moment, one way or the other, except to those immediately interested in them. Our opinion is decidedly, that the good effected by the Society has much outweighed the evil; but we are perfectly open to conviction, if those who think otherwise will be pleased to give us facts and reasoning, instead of misrepresentations and revilings. We are quite aware that there is an outcry against the Apothecaries, but we are always suspicious of the disinterestedness of those who have recourse to clamour; and we know that the parties who have been most active in addressing the Home Secretary, are—first, certain graduates or diplomatists of Edinburgh, who have been rejected by the Apothecaries, and—secondly, those teachers in the northern metropolis, who have a direct personal interest in the matter.

One thing is quite clear: that if the demands of the petitioners be complied with, it will place all the general practitioners who are now settled in England in a precarious and most unpleasant position,—both because it will admit an immense number of competitors from beyond the Tweed, who will dispute every shilling of their income with them, and because it will

annihilate any protective influence which is at present afforded against the encroachments of those who have received no medical education at all.

Any one, it is obvious, may set up as a general practitioner in England, if all those holding degrees or diplomas of any of the Colleges or Faculties of England, Ireland, or Scotland, may do so—at least so far as the Society of Apothecaries are concerned; for it is not to be conceived that the latter body would be such fools as to venture upon prosecutions which it would no longer be their peculiar interest or province to conduct; while, on the other hand, they never could be certain but that the party was designedly leading them into Court, with the intention when there of drawing from his pocket the diploma of one or other of the above-mentioned corporations.

Upon the whole, as we have said, the question is a serious and important one—not suited for hasty legislation, nor to be disposed of in the adroit manner that has been attempted. We are happy in being able to add, that the Bill has been postponed, so as to allow of both sides being heard; and an opportunity is thus given to those whose interests would be compromised, of making their statement, as well as to those who seek to be the immediate gainers. Let the points be fully, freely, and fairly discussed, without reference to petty jealousies, or individual instead of public interests, and then we doubt not but that the Government and the Parliament will come to a sound and satisfactory decision.

PUBLIC (?) MEETING IN FAVOUR OF THE CONCOURS.

A “public meeting,” of which no one heard till after it had taken place, and at which Dr. Augustus Bozzi Granville presided, was held last week, and adjourned (we dare say not without good

and sufficient reasons) till Tuesday the 7th. Whether any person attended on the second occasion we know not, but we are quite satisfied that a report of the proceedings will be published at all events; and we therefore, as in duty bound, hasten to make our readers acquainted with the important events which are passing in the medical world. The purpose of these *public* meetings is to petition parliament against suffering the governors of medical charities to elect their own officers, as heretofore, and to compel them to adopt the *concours*—a mode of appointment which, as we have lately shewn, gives so much satisfaction in France, that at the election now pending only eight out of ten candidates have retired in disgust. It is undoubtedly highly proper that in England, where the hospitals and similar institutions are supported by private contributions, all the arrangements should be precisely the same as in those countries where they are government concerns, and supported by the public money. It is quite apparent that limiting the patronage would have a direct effect in increasing the subscriptions; while placing the appointments under the control of the minister, as the *concours* does, would be in keeping with the spirit of the age, which tends so remarkably to surrender to the government all those privileges which have hitherto been enjoyed by the public. We therefore entirely approve of the object of these meetings, as well as of placing Dr. Granville in the chair. It is always desirable on such occasions to obtain the sanction of persons of weight and influence in the profession: besides which, the chairman being physician to *only three* public institutions, is perhaps able to speak from personal acquaintance with the evils of the present system; and may, in his own experience, have known it lead to the exclusion of modest merit.

ON FIBRO-CELLULAR TUMORS OF THE UTERUS.

BY BARON DUPUYTREN.

From the "Leçons Orales," published periodically, under the Baron's inspection.

History of two Cases of Polypus Uteri.

DURING January of the present year, two patients were admitted, nearly at the same time, into the surgical wards of the Hotel

Dieu, each having what is commonly called polypus of the uterus. The one, aged about 46, complained of having had for a month a discharge of blood from the vagina, to which, for the last eight days, had succeeded a whitish, sanious, and slightly fœtid discharge. She asserted that she never had, till then, experienced any symptom of a uterine affection, but this statement was disbelieved by M. Dupuytren, as her situation in life rendered her likely to overlook any complaint which did not actually interrupt her usual vocations. She had been examined by a private practitioner, and told that she had a cancer of the uterus. The bowels had been constipated, probably owing to the pressure of the tumor; but this symptom was removed by laxative clysters, and she was so much relieved that she had nearly persuaded herself she was well, and thus declined the operation. The tumor, however, is as large as half the fist, with superficial ulcerations.

The other patient was 48 years of age. Observe the coincidence as to age in the two: it is, in fact, towards this period of life—that is to say, from 38 to 50—that organic diseases of the uterus most frequently supervene. During a year, this last patient had been affected with a red discharge, constant and very abundant, which she called the menses, and which she explained, without being much alarmed, on the principle that women arrived at her critical age often suffer in this way. During the last month, the discharge had become sanious and very offensive. She had also experienced frequent pains in the loins, extending to the groins and thighs, and a painful sense of weight and pressure about the anus: it is of this that she at present complains most. I have examined her, and discovered the presence of a polypus at least as large as the fist, having a pedicle about the thickness of two fingers, taking its origin from the interior of the organ, and embraced by the neck of the uterus as by a ring.

Parallel between the cases.—Both are of the same age; the tumor is in both nearly of the same size, occupies the same situation, and gives rise to the same phenomena: first a discharge of blood, and then of fœtid sanies. But in one the surface of the tumor is smooth, in the other it is unequal; in the former the substance is dense and resistant, while in the latter it is soft and yielding. In the one, the discharge of blood has only been present for a month, and is but little fœtid; in the other it has continued for a year, and is exceedingly offensive. From all this, it may be inferred that the tumor has not degenerated in the first, and that the operation might therefore be delayed a short

time without risk; while there is already degeneration in progress in the second, requiring its immediate removal, and that even this offers but an uncertain prospect of success.

Besides, the last patient appears to suffer much; she experiences severe pain in the loins, with a painful sensation in the vagina and rectum. Nevertheless she dislikes the idea of the operation, and I have not been able to reconcile her to it; neither would the present moment, perhaps, be favourable for it. The other patient, on the contrary, does not suffer at all; she is perfectly resigned, and her general state is favourable, and I shall therefore operate forthwith.

Operation.—On the 21st of January the patient was brought to the amphitheatre, and placed upon a lithotomy bed; the legs and thighs bent, widely separated, and retained by assistants. A fresh examination was then made; a pair of forceps *de Museux* introduced, and the blades fixed in the substance of the tumor; moderate and continued traction was then applied, while the patient was directed to make bearing-down efforts, which she did with intelligence and effect. The tumor being now near the orifice, another pair of forceps was fixed on it, and gentle force continued. The tumor at length presented itself at the external aperture, and then passed it, the neck of the uterus being perceptible. The operator then divided the pedicle of its root, by means of two or three cuts with a pair of strong curved scissors, and so as to leave no trace of the diseased textures remaining. The section was not attended by any pain, nor did it produce any hæmorrhage; nevertheless, the orifices of a great number of blood-vessels were observed on the cut surface of the pedicle. After the operation, M. Dupuytren made the patient remain in the theatre for some time, that the numerous spectators might satisfy themselves whether or not any bleeding occurred. At the end of more than a quarter of an hour, the smallest quantity of blood had not been lost. Next day, the quantity which had escaped in twenty-four hours might be estimated at one or two spoonful. I confess, however (said M. Dupuytren), that although this entirely refutes one of the chief objections brought against my mode of operating, yet I am far from congratulating myself that so small a quantity of blood has been discharged. A loss of blood, more or less considerable, is always useful after operations of this kind; rendering the patient much less exposed to the inflammatory mischief which is apt to follow. At present nothing indicates the least disturbance; but she must be watched, and, on the first symptom of in-

flammation, general and local bleeding, as well as the other antiphlogistic means, shall be vigorously adopted.

[She recovered rapidly, and was discharged the beginning of February.]

The second patient, though under much less favourable circumstances than the preceding, was yet encouraged, by the result, to submit to the operation, which was proceeded in on the 22d January, in the same manner as the former. The tumor being seized with the pincers, yielded and tore under the gentlest traction. When it was brought to the external orifice, it presented a greyish gangrenous mass, which it was found could not be brought down farther without breaking it. The pedicle was therefore cut as near its origin as could be effected, by carrying the scissors up into the vagina; but some portion of it was unavoidably left behind. This, like the former, was unattended by hæmorrhage, neither was it followed by sanious or foetid discharge. Next day, the patient had no symptoms except some pain in the hypogastric region, which led to the application of fifteen leeches to the thighs.

On the fourth day she was seized with rigors, and complained of severe pain in the lower belly, umbilicus, groins, and back. Leeches were again applied. On the fifth day she was in a state of indescribable uneasiness; she had frequent rigors, and great general disturbance; and she died on the night of the 27-8th—that is, on the seventh day after the operation. On opening the body, the uterus was seen to be very large, and all the viscera of the pelvis were united together by old adhesions; there was purulent matter between the uterus and bladder. The increased size of the viscus was found to depend upon the augmented thickness of the parietes, as it contained no other polypus: both within and without it was of a violet red colour.

Signs of Disorganization in Uterine Polypi.

I have observed the same phenomena, said M. Dupuytren, in all the cases of polypus which have been abandoned to themselves as we met with in these two patients. So long as they have only a red or white discharge, there is no fætor: examine them, and you find a tumor which is throughout of equal density; introduce the speculum, and you see a white or rose-coloured body, smooth and polished. But if there be sanious discharge, there is then horrible fætor, and, when examined, you find a soft fungous tumor, extending over a surface which bears a relation to the period which has elapsed since the supervention of the symptoms in question. It is also at this time that the constitution begins to suffer in a severe degree—that

the skin becomes of a pale yellow—that fever sets in—that emaciation advances—that the appetite and sleep are lost. There appears to be a decided coincidence between the appearance of gangrene, as marked by the foetid sanious discharge, and the commencement of the cancerous degeneration. This change takes place first at the inferior part of the tumor—that which is exposed to the contact of the air; the body of the polypus is affected first, the pedicle last. The phenomenon cannot, therefore, be ascribed to the constriction of the neck, as has been done by some. It is, however, but rarely that the pedicle is entirely detached from its insertion in the uterus by gangrene; so that, in fact, spontaneous reparation by slough is exceedingly uncommon—so much so, that I have only met with one instance of it. The case was as follows:—

Case of spontaneous reparation of a Polypus of the Uterus.

Frances Pelegrini, aged 33, an Italian, of dry fibre, and who had menstruated at 18; mother of four children, and having had favourable accouchements, the last at 28. From this period the menstruation was sufficiently regular, except that each period was followed by a white discharge of some days' duration. In August 1816, without obvious cause, she was seized with violent flooding, but unaccompanied by any other disturbance of the sexual system. She continued her avocations, which were but little laborious, and she did not perceive that doing so increased the discharge. In February, 1817, she had pains in the loins and groins; she employed astringents internally, believing that it was but an ordinary uterine hæmorrhage, for she had not been examined. She came to the Hotel Dieu, March 18th, complaining of continual discharge in considerable quantity, and alternately red and white; with some slight pain in the loins, and occasionally extending to the groins. There was not that paleness which attends long-continued and repeated hæmorrhagy; there was no difficulty in passing the urine or fæces; no sense of weight in the perineum. The touch alone disclosed the nature of the malady. The finger introduced into the vagina encountered a cylindrical body, softish, of the size of the fore-finger, passing about an inch and a half out of the uterus, and in the neck of which it was engaged. The open orifice of the os uteri easily admitted the point of the finger, which passed along the entire circumference of the tumor, but could not detect its insertion: this, then, was a polypus. As it was not large, and had not the same consistence as uterine polypi usually have, M. Dupuytren intended to

tear it off with a pair of pincers having large blades, but postponed the operation to the fourth day. The patient was then conducted to the theatre, and placed on the edge in an elevated bed; the finger introduced into the vagina did not discover the tumor which had previously been felt, and the patient now stated, that, the evening before, she had voided a dark elongated body, which she had taken for a clot, and had not kept. During two days there was a red discharge, which then diminished, and by the third day was entirely white: this also disappeared on the sixth day. On the eighth day, the os uteri was entirely closed, and the uterus itself seemed to have regained its natural dimensions. On the 2d of April she left the hospital almost well, but, six days after, voided another body, analogous to the first; from which time all discharge ceased.

What opinion are we to form, regarding the disappearance of a polypus, the existence of which had been ascertained by several persons? Had it ascended into the uterus? This is feasible to those who are aware of the manner in which these bodies arising at the fundus uteri descend into the vagina; for it is known that they carry the fundus down with them, producing a greater or less degree of eversion, and, after the division of the pedicle, the fundus re-ascends. Besides, there was recently, at the Hotel Dieu, a patient with polypus, in whom it descended into the vagina and returned up into the uterus alternately. There are uterine polypi of a fibrous nature, which become spontaneously detached without their pedicle being destroyed by gangrene; and these tumors are developed almost immediately beneath the inner membrane of the uterus: scarcely have they passed the neck when their external layer, being very thin, breaks; and then they drop off, after having given rise to some discharge. Instances of this kind are quoted by various authors, and, among others, by Madame Boivin, in her *Treatise on Diseases of the Uterus*.

Reasons which induced M. Dupuytren to abandon the Ligature and employ Excision.

Two methods of operating are at present adopted by practitioners with regard to these uterine tumors—viz. *ligature*, which is adopted by a great number of surgeons, and *excision*, which has been exclusively adopted by M. Dupuytren for many years. The many inconveniences (said he) which attend the former, have led me to prefer the other. 1st. The ligature is not easily applied; a fact sufficiently proved by the number of instruments which have been contrived with a view of effecting this object: besides which, it

scarcely ever includes the whole of the pedicle, and this gives rise to the tumor growing again as before. 2dly. What has above all led me to abandon the ligature, is the consecutive effects. The patients continue in a satisfactory state for two or three days after the operation, but, at the end of this time, a foetid discharge takes place, resulting from the mortification of the tumor; symptoms indicative of the absorption of purulent matter supervene, and the patient sinks, notwithstanding the use of tonics and antiseptics. After death, traces are found of violent uterine inflammation, extending to the adjacent parts. Sometimes, indeed, those appearances are not found; but still the conviction remains that the patients have been destroyed by purulent absorption. I have notes of eight or ten such cases, which have occurred in this hospital; but I have never seen these consequences result from excision. 3dly. The ligature is very painful, and continues till the tumor is detached; while the section is unaccompanied by pain; the patients, indeed, being immediately relieved. 4thly. Sometimes the ligature gives rise to pain, which extends to the iliac fossæ, and excites inflammation in the appendices of the uterus, which becomes fatal after having, by the mildness of the disturbance, excited hopes for some days of the patient's recovery. 5thly. Inflammation of the veins about the pelvis is another consequence apt to follow the ligature, but which I have never seen from excision. 6thly. The coming away of the ligature is usually followed by the cicatrization of the parts; but this does not always happen, and sometimes the discharge, &c. continue, and to such an extent as to prove fatal. M. Dubois states (*Dict. des Sciences Médicales*, art. *Polype*), that he has repeatedly seen bleeding come on after the fall of the ligature, and the patients perish from this cause. 7thly. The ligature, even by those who adhere to it, is allowed to be inapplicable in cases where the tumor is formed almost entirely of the uterine tissue, and where the pedicle is very large; indeed its application is impossible where the surface at which the polypus adheres is very extensive. In this case, however, nothing forbids excision—nay, it is the only means which is applicable. 8thly. These dangers and inconveniences attendant on the ligature being avoided by the immediate division of the pedicle, it remains to weigh against them the fear of hæmorrhage. Now long experience and numerous trials shew that this hæmorrhage is exceedingly rare. The number of polypi removed by excision, by M. Dupuytren, during the last twenty years, amount to from ten to fifteen annually. Take the

smaller number (ten); this, multiplied by twenty, will give us 200. Well; in this large number, hæmorrhage has only taken place twice—once in the hospital, and once in private practice; while, in both instances, it was promptly and easily arrested by plugging. One of the patients, indeed, died, but not till the twenty-fifth day after the operation, having laboured under extensive peritoneal inflammation, as was demonstrated by the post-mortem examination. M. Velpeau, in eight cases, has never met with it. Such are the dangers of hæmorrhage so loudly proclaimed!

[It is to be observed, that M. Dupuytren always employs a pair of seissors—never a knife: perhaps the manner in which the former act, by bruising as they cut, may serve to explain the infrequency of bleeding.]

Definition of Fibrous Tumors—their different situations.

These fibrous bodies, or tumors, are of various forms, generally more or less rounded, and composed of accidental tissue, analogous to that of tendons or the ligaments about joints. They become developed in all the regions of the body where fibrous element abounds, particularly where it is in direct contact with cellular texture. But the uterus is one of the organs in which it is most commonly met with, and the tumors there occupy different positions, the distinction of which is of very great importance.

1. Some take their origin from the external surface of the uterus, between the substance of that organ and the peritoneum, by a pedicle, which is sometimes very thin. This pedicle, and some laminae of cellular texture, appear in such cases to be the only bond of union which the tumor has with the uterus: they project into the abdomen, raise the peritoneum; and from the smallest size may increase to that of a child's head: they have been known to weigh ten, fifteen, and even twenty pounds.

2. Others form in the walls of the uterus, but the proper tissue of this part enters not into their composition: they become developed by separating its fibres, and are never united to it by continuity of texture: indeed they are sometimes so much insulated that at the first view they appear to be encysted. They have no pedicle: their growth is slow, but sometimes acquires the size of a person's head: sometimes they are equally developed in all directions: sometimes they extend chiefly in one way. Tumors of this kind are very common, and almost all beyond the reach of an operation, as they would require the extirpation of the entire uterus.

3. There are some tumors which arise nearer one surface than another of the

uterine parietes, extending towards the external or internal surface: sometimes these are pedunculated, at others they are not. In the latter case they approach those above described; in the former they resemble those which follow.

4. These tumors are often situated on the inner surface of the uterus, and either merely project into the cavity, or are actually furnished with pedicles, which last is the most common. These are the fibro-cellular polypi *par excellence*, and are composed of a root, a neck, or pedicle, and a body often assuming the appearance of a mushroom. In other cases they are covered by a very fine adherent membrane, formed of that which was designated by Bichât the mucous membrane of the uterus. When the kind of hollow which surmounts the body of the polypus is completely rounded it is in vain to seek for the pedicle; it cannot be found unless it be very much elongated, and the polypus, having escaped from the neck of the uterus, has projected more or less into the vagina. The part inserted into the lining membrane of the uterus is called the root, and by this the tumor receives its nourishment. It is formed of nutrient vessels of veins, lymphatics, cellular and fibrous tissues. This is very important to be known, for if these tumors grow again, when they have been cut as close as possible to the surface of the uterus, this event is to be attributed to a portion of the morbid textures being left behind.

Importance of ascertaining the form of the Polypus.

You have seen that some fibrous tumors have a pedicle, while others have not, and that this difference in general depends upon the situation which they occupy. A general division may thus be formed of pedicled and non-pedicled growths; or, in common language, fibrous *polypi* and fibrous *tumors* of the uterus. The length of the pedicle varies very much: the more the polypus extends itself, the more must its pedicle be elongated: the longest, therefore, are found in those cases where the polypus descends far into the vagina. The pedicles contain arteries: how then is it that their division does not produce hæmorrhage. The arteries, indeed, are sometimes large; and M. Cuillard, who fell a victim to the cholera, had made a preparation of a polypus in which we observed a very considerable artery, the division of which, nevertheless, had not caused hæmorrhage.

The form of these tumors varies: it is usually globular or oval, but not unfrequently angular and furrowed when they descend into the vagina, and when they are large they are almost always divided

into lobes. It is of the greatest importance, with regard to the diagnosis, to attend to the general disposition of the tumor. The following is a proof:—

The wife of a gentleman in the environs of Paris consulted one of the most celebrated surgeons of the capital. He examined her, and found a tumor; remarked its fœtid odour, and announced to the husband that his wife had cancer of the uterus, and had not three months to live. She afterwards came to me. I had learnt by experience how deceitful the touch is, and the necessity of making such examinations with care. I found a tumor, of considerable size, which I was able to pass the finger round. Carrying the finger higher, I discovered a pedicle; and yet higher, I recognized its insertion into the neck of the uterus. I then stated that the tumor might be easily removed, and that the patient would soon be cured. The husband asked me if I was quite sure of what I said, and prayed me to examine again. I did so, and came to the same conclusion. He then told me what had been said by the surgeon above alluded to, and this made me fear some mistake on my part, so that I examined a third time, but every thing convinced me of the correctness of my diagnosis. The operation was performed, and the patient was quite well in a fortnight.

Structure of Uterine Polypi.

What proves the mucous nature of these tumors, and by inverse reasoning the mucous nature of the inner membrane of the uterus, is, that they take on all the actions of mucous structures—not only as regards the discharges which take place from them, but also as to the kinds of ulceration which they assume. These ulcerations, indeed, are frequent about the neck of the uterus, and it is of importance not to confound them with cancerous affections. I have seen females who were said by surgeons of repute to be affected with cancer who had only simple ulcerations, which were readily cured by a few applications of caustic. These simple ulcerations are to be recognized by their redness, their irregularly rounded form, their whitish base, formed of a layer of fibrous cellular tissue, not easily distinguished from the proper tissue of the polypus.

When the polypi are divided immediately after their excision, they present a dead-white appearance: they resemble exceedingly intervertebral substance, being eminently fibrous. But they also contain another tissue—I mean cellular membrane: generally, however, more dense than elsewhere. Sometimes these two are in about equal proportions, but occasionally one preponderates over the other, and it is on

this preponderance that the subsequent changes depend. If the fibrous element abounds, the polypus does not degenerate, or if at length it does so, it passes into an ossific state. If, again, the cellular tissue abounds most, the polypus degenerates into carcinoma; the substance inflames; becomes softened; the surface becomes uneven and ulcerated; then commences sanious discharge, with fœtor, the sure indications of disorganization having begun. The constitution then suffers. The polypi are then converting into medullary tumors: in a word, into carcinomatous degenerations. The same changes may be brought on by accidental causes, particularly by the development of inflammation of the mucous or peritoneal coverings. But what distinguishes these from the spontaneous degeneration is, that this last proceeds from the centre to the circumference of the tumors, while the former observes an opposite course. In fact, it is proved that all the fibrous, cancerous, fungous, or fibro-cartilaginous and bony substances which have been considered as so many natural productions, each of a different cause, are only different degrees and successive transformations of the same disease. But it results that if these tumors be removed at their origin, and before any degeneration has come on, there is very little risk of their return; and that the longer their extirpation is delayed, the greater the danger of this. Again, the operation, which is very easy at first, becomes extremely difficult when the disease has passed its enveloping tunic, requiring a much greater loss of substance to insure its entire extirpation.

Frequency of Uterine Polypi at different ages.

The disease which we are occupied in considering was formerly looked upon as very rare. When Levret began to study it he required seven years to procure three cases on which to apply his method, and others speak of it as still more uncommon; nevertheless, it is now well known that the fibro-cellular polypus is one of the most frequent of uterine affections. In 1770 Portal stated that of twenty uteri which he examined thirteen had polypi; and according to M. Dupuytren there are few women of a certain age without some uterine tumors of this kind.

Without entering into hypothetical opinions regarding the predisposing causes, there are two facts which may be mentioned. It appears that the period between forty and fifty years of age is that which furnishes the greatest number of polypi of the uterus. On the other hand, the assertion of Bayle, often repeated without examination, is completely erroneous, namely, that celibacy and sterility have an influence in producing the dis-

ease. The number of cases I have consulted amounts to 62. M. Velpeau has communicated to me the histories of eleven patients treated by him: many are to be found in the works of Mad. Boivin, MM. Recamier, Bayle, Marx, &c. With respect to age, in general that period only is noted at which the patient has come under the notice of the practitioner; but I have endeavoured to establish another and more important one, namely, that at which the symptoms of the disease first shewed themselves, the latter being in reality the true period of life which has most influence on their production. But of the sixty-two cases above alluded to five must be deducted, the history being incomplete. There remain 57, and in them the symptoms first manifested themselves in—

1	from 15 to 20.
10	.. 20 to 29.
19	.. 30 to 39.
23	.. 40 to 49.
3	.. 50 to 59.
1	.. 60 and upwards.

Thus the period which furnishes the greatest number is from 40 to 50, and next that from 30 to 40.

The ages of the patients when treated, comprising the whole 62, stand thus:—

20 to 29	.. 8.
30 to 39	.. 18.
40 to 49	.. 24.
50 to 59	.. 6.
60 and upwards,	5.
Age not marked,	1.

62.

2. *Effects of Marriage and Celibacy.*—With regard to marriage or celibacy, we of course are to consider as married, and class with them all those females who have cohabited. Of the 62 there are four, with respect to whom this circumstance is not mentioned: we have, therefore, left 58. Of these 54 were married, or females who had had intercourse: 4 only were females presumed not to have cohabited.

3. *Effects of Fecundity and Sterility.*—Let us next take the opinion of Bayle with respect to sterility. We have only 51 in whom this circumstance is ascertained, and they stand thus:—

Married women, having had from 1		
to 10 children.....	39	} 42
Unmarried, ditto.....	3	
Married women, having had no		
children	8	} 9
Unmarried women having cohabited without having children .	1	

Among the women who had children, the great majority had more than 3: many had 5; several had 7, 8, or 10.

4. *Effects of the state of Menstruation:—*

Regular to the period when the disease commenced	41
Irregular for some years prior to disease	5
Irregular during the whole period	6
Regular, but having had leucorrhœa during 13 years: having had 6 children, and being aged 48	1
State of the menstruation unknown	9

These data with regard to menstruation present but little interest; but those connected with the age, the state as to marriage or celibacy, and as to fecundity or sterility, are positive, and too obvious to require that they should be pointed out.

[The preceding lecture is condensed by the omission of numerous repetitions which occur in the original. We have taken care, however, to lop off nothing but the exuberant growths, leaving all the rest untouched.—TRANSLATOR.]

TREATMENT OF INFLAMMATION OF THE LUNGS

By large Doses of Tartarized Antimony.

THE following is a resumé of the experience of Dr. Munaret on this subject, taken from the *Gazette Médicale*, wherein the details are published.

Number of cases of acute inflammation of the respiratory organs, treated between the 28th of July, 1831, and the 15th of January, 1833, thirty-seven—viz. pleurisies and pleuro-pneumonies, 22; pneumonies, 12—which is about the rate of one case for every fourteen days.

Seasons.—Spring, 6 cases; summer, 8; autumn, 3; winter, 20.

Sexes.—Women, 17; men, 20.

Ages.—Among the females, between ten and twenty, 2; between twenty and thirty, 6; between thirty and forty, 4; between forty and fifty, 2; between fifty and sixty, 1; between sixty and seventy, 2.

Among the males, between ten and twenty, 6; between twenty and thirty, 3; between thirty and forty, 4; between forty and fifty, 6; between sixty and seventy, 1.

Results.—Recovered, 34; died, 3—viz. a blind idiotic girl and paralytic woman, affected for a long time with organic disease of the lungs; a woman who was doing well when some other medicine was substituted for the tartar emetic, unknown to Dr. Munaret.

Description of the Method.—In most patients who are of sanguineous temperament, the practice commenced with a bleed-

ing at the arm, repeated according to circumstances. In the more aged and feeble, the application of leeches to the chest was preferred. The *Rasorien* potion was administered thus:—

No. 1.—Distilled Water, $\mathfrak{z}\text{v}$.; Tartarized Antimony, gr. v.; Laudanum, gtt. v.

No. 2.—Distilled Water, $\mathfrak{z}\text{v}$.; Tartarized Antimony, gr. viii.; Laudanum, gtt. viij.

No. 3.—Distilled Water, $\mathfrak{z}\text{v}$.; Tartarized Antimony, gr. xii.; Laudanum, gtt. xvi.

A table-spoonful every two or three hours; cold water in abundance during the intervals.

As the disease declines, blisters, squills, &c.

Progress of the Disease.—Eleven days the mean duration. Diaphoresis is the constant indication of the medicine acting favourably; vomiting alone, or accompanied by purging, fourteen times in thirty-seven—viz. in eleven women and three men. A few drops of laudanum added to the potion overcomes this effect. At other times, and indeed more frequently, purging takes place without vomiting, and without aggravating the principal affection.

Doses of Antimony.—From five to sixty grains, and upwards, in three days; mean quantity during the treatment, sixteen to twenty grains.

Precautions.—Patient and those about him to be made acquainted with the probable effect of the medicine, otherwise it is apt to be discontinued in the absence of the practitioner.

Inference.—Tartar emetic, administered in large doses, and judiciously continued, with antiphlogistics and derivatives, is, to acute inflammations of the chest which are not complicated, what quina is to ague.

ROYAL INSTITUTION.

Friday, May 3, 1833.

On the action of Lime, Carbonic Acid, and Water, on each other.

THIS subject was taken up at a short notice, and treated with his usual ability, by Dr. Faraday. The lecturer began by giving a rapid view of the abundant and diversified sources of the carbonate of lime in nature; whence he proceeded to notice the mutual action of carbonic acid and lime with the intervention of water, shewing particularly how an excess of carbonic acid will redissolve the suspended carbonate, and calling the attention of the audience to various changes effected both by

nature and art in consequence of this property. The formation of stalactites and incrustations, the use of lime as a manure, and the addition of the same substance for the hardening of roads, were adduced as instances. But he pointed out the curious fact, that even caustic lime has no affinity for carbonic acid unless water be present as an intermediate agent. From this, Dr. F. proceeded to notice the theory which is found in all the elementary works on chemistry, relative to the formation of caustic lime: they all state that the effect is produced by expelling the carbonic acid with heat; a statement which is imperfect, and calculated to mislead. Berzelius alone seems to have touched upon the true theory, and notices the necessity which there is in the process for the presence of water. Further, the lecturer described the extraordinary affinity of carbonic acid for lime when chemically combined; no degree of heat, not even a white heat, being sufficient to separate them, unless water be added. Mr. Brunel, jun. when he wanted a large supply of carbonic acid, attempted to procure it from the carbonate of lime exposed to the most violent heat in iron retorts: but it was all in vain, until, at Dr. Faraday's suggestion, he added steam, and then the gas came over in abundance. The agency of water, in essentially aiding the expulsion of carbonic acid, does not seem to have escaped the observation of Dr. Wollaston: his hint to Dr. F. for procuring caustic lime shews this: "If you want to procure lime for the laboratory very caustic," said he, "you must first burn it, then slake it, and then burn it again." The splendid experiments of Sir James Hall, who was enabled even to fuse carbonate of lime, exposed to a violent heat under great pressure, depended on this principle: and in the same way we might account for the presence of masses of pure carbonate of lime among the substances thrown up out of volcanoes, though such a fact might seem at variance with another belonging to the same source, namely, the occasional occurrence of native caustic lime in volcanic districts. Dr. F. mentioned that a specimen of the latter sort from the Apennines was submitted to him for analysis by Sir H. Davy in the year 1815, and a paper on the subject may be found in the first volume of the *Journal of the Royal Institution*. The latter part of this interesting lecture was devoted to an account of the various methods of lime-burning, with remarks on their respective merits.

In the library, the great attraction of the evening was a superb display of warlike accoutrements and arms, from Cutch, in Upper India.

ZOOLOGICAL SOCIETY.

Annual Report.

At the annual meeting of this Society, held on Monday, 29th ult., at the Royal Institution, Lord Stanley in the chair, the report was read, from which we select the following particulars. There are at present on the books of the Society 2330 Fellows, 22 foreign members, and 120 corresponding members. The number of visitors to the gardens in 1832, was 218,585; and to the museum, 7134. The admission fees and annual subscriptions during the last year, amounted to 4312*l.* 8*s.*; and for admission to the gardens during the same period, 9001*l.* 16*s.* had been received: being 3058*l.* more than had been taken in 1831. Upon a division on the question, whether the gardens should be kept open all day on Sundays, or closed till after one o'clock? the former proposition was adopted by a considerable majority.

M. DESGENETTES.

THIS veteran and distinguished professor was recently attacked with hemiplegia, while delivering a lecture. Active measures were promptly employed, and good hopes are entertained of his speedy recovery.

NOTICES.

Mr. Kilby's Sketch of Medical History is inadmissible, as totally destitute of practical interest.

For much the same reason we are obliged to decline Mr. Bracy Clarkes paper (supplementary) on Cholera. It has been returned to the address directed, New Bond-Street.

Dr. Blackmore's communication has reached us.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE CHEST.

—
HOOPING-COUGH.

THE next disease of which I will speak, and which is very much allied to the last in some respects, is hooping-cough.

Etymology—This disease is called, in English, *hooping-cough*, from the peculiar noise attendant upon the cough. Sometimes it is called *chin-cough*, because it attacks children particularly, and *chin*, I suppose a corruption for *kind*, is the German for child. In Latin it is called *tussis*—cough; or, to shew its intensity, *pertussis*—much cough.

Symptoms.—This disease is easily known when it has been once seen. There are occasionally fits of violent coughing, with short expirations—a volley of them, and then one deep, long, hooping, crowing inspiration; and these are many times repeated. A quantity of viscid phlegm is spit up, and very often the child vomits. The cough is exceedingly severe, every muscle is put into action, the face grows red, the eyes run, and then in an instant the child, although apparently about to be strangled, unable to stand, runs about and plays as if nothing were the matter with him. This is very commonly seen, and the cough will come on day after day. At first there is generally some catarrh and bronchitis with it, and this is of various intensity as well as the cough. Sometimes the bronchitis is very considerable, so

that the child has a constant difficulty of breathing, constantly a quick pulse, constant heat, and is exceedingly ill. The disease, although to a great degree spasmodic, and sometimes almost entirely so, is, on the other hand, occasionally in a high degree inflammatory. When it has been inflammatory, and the child recovers, after the inflammatory state has subsided, the spasmodic cough will frequently continue, and even for many months.

Premonitory Symptoms.—The first notice of the disease is generally occasioned by the extreme violence of the cough, or by a hoop; but very frequently it is not noticed at all till the child hoops, and then there is no doubt of the nature of the disease. In fact, you are never justified in saying that the disease exists till the child hoops. If the disease prevails in the neighbourhood, and the child coughs more violently than usual, it will turn, in all probability, as people say, to the hooping-cough. But if the disease be not fully formed, one cannot say with certainty that it is the disease unless the child hoops, or the disease is existing extensively in the neighbourhood.

Bronchitis usually present when it proves fatal.—If the bronchitis be violent, or if it continue, not violently, but for a length of time, the child may die. As a mere spasmodic affection, it does not generally destroy life. In the greater number of cases where children die, there is a violent bronchitis, or an extensive bronchitis, and a violent or extensive inflammation of the substance of the lungs.

Morbid Appearances.—On opening children who have died of this disease, you occasionally find very little the matter in the lungs, and the child may have died from something else; for the disease has a great tendency to produce hydrocephalus—to produce convulsions, and various affections of the head, such as we see in children. It is one of the great calamities attending the disease, that the effects of it

are so fatal. There is such continued difficulty of breathing, such violent cough, that it overstrains the vessels of the head, over-distends them, and the consequence is such irritation of the head, such congestion of the head, that hydrocephalus continually occurs. I know that violent coughing will overstrain the vessels of the head and produce great mischief; for I saw, not long ago, an infant that had never been well from the moment that it had coughed violently: it was so strained that the parents fancied it would die from time to time; from the instant of the coughing, the head drooped, convulsions came on, and it ultimately died of convulsions, although it was very well—having comparatively nothing the matter with it (at least with the head), having only a common cough at first, such as other children in the family had—till it was seized with this violent cough. Thus you see children dying from hooping-cough, or rather from the effects of it than from the disease itself, and yet, after death, you can discover very little in the lungs. But frequently, generally indeed, on examining the lungs you find a large quantity of mucus in the bronchiæ; you find the mucous membrane red, thick, soft, and pulpy, and increased in thickness, so that there is clearly bronchitis. You also frequently find the lungs very solid; the air cells have become inflamed, and they are very much hepatized. I have opened children who have died of this disease, and nearly the whole of the lungs have been like liver; they did not collapse, and on pressing them you could scarcely diminish their bulk in the least. When these circumstances take place, on listening to the chest you hear the common signs of bronchitis—you hear the silvery rattle which occurs in the breathing of adults, and you hear the breathing excessively loud and rough throughout the chest.

Duration.—The disease may destroy a child in two or three weeks, or it may not destroy it for many weeks; but after the disease has lasted for six or eight weeks, it generally gives way; it seldom continues longer. Children, however, from the very slightest cold, are apt to hoop again. Some will hoop the greater part of a twelvemonth, and some, when they have once had the disease, if they catch a severe cold, at a more distant period even than that, will be observed to hoop.

Most frequently attacks Children.—It affects children by far the most frequently; but it will also affect adults. I heard that the late Archbishop of Canterbury had it a short time before he died.

Frequently Epidemic.—It is frequently an epidemic disease. It does not in general occur more than once, excepting in a mere spasmodic form, when the parts are thrown

into such a condition as to produce hooping, although the real disease does not return.

Causes.—It is supposed by some to depend on a specific contagion; some deny this, but others assert it. I was always taught that this was its source, and I never thought of doubting it; but others have done so, and I suppose they have a reason for it.

Any irritation whatever will provoke a paroxysm when a patient has the disease. If a child be put in a passion, or you move it about quickly, or give it any thing stimulating, then a paroxysm will take place. There may be various exciting causes of a paroxysm, although the peculiar exciting cause of the disease, I presume, is only one—either a specific contagion or something peculiar.

When a child vomits, it is generally considered a good sign. If there be no vomiting with the cough, it is observed by those who have most experience that the child gets worse. Dr. Gregory knew a lady who never hooped in the disease, and therefore it was hardly hooping-cough, but she always fainted. The disease prevailed in the family, and she had as violent a cough as the rest, but at the time she ought to have hooped, she fainted.

Danger in proportion to other Symptoms.—The danger is in proportion to the other symptoms—that is to say, the affection of the head, and the symptoms of bronchitis and peripneumonia; and of course there is more danger the younger the child is. It is a very dangerous disease when it occurs in infants. Those who suppose that the disease arises from contagion, consider that it is latent, from a few days to a few weeks; and they suppose that the disease itself, when it occurs in an individual, is not capable of communicating contagion beyond a month or six weeks, just as is the case with other contagious diseases. Gonorrhœa, for example, after a certain lapse of time, although nobody will venture to fix the period, is not contagious.

Treatment.—The treatment, gentlemen, of hooping-cough is two-fold—as it respects the inflammatory condition of the parts, and the spasmodic.

As it respects the Inflammatory State.—The most important thing by far is to remedy the inflammatory state—the bronchitis or peripneumonia. If it be found that there is a constant oppression of the breathing, with spasmodic attacks, and a violent cough at times, an accelerated pulse, together with pyrexia, sonorous, sibilous, and crepitous rattle, it will be evident that there is inflammation of the bronchiæ or the substance of the lungs—the tubes, or the air cells, or both; of course that must be remedied in the usual way. You

might give all the anti-spasmodics, all the narcotics, and all the medicines that are supposed to have a direct influence over spasm, and yet do no good; in fact, you would make the patient worse, and if nature were not to get the better of you, and cure the individual, there is every probability that great mischief would be done. It is therefore highly important to ascertain the existence of inflammation, and remedy it, if possible, in the usual way—by taking blood from the neighbourhood of the chest, occasionally by bleeding in the arm, if the patient be old enough, but particularly by local bleeding, the exhibition of mercury and of emetics. In the greater number of cases, the inflammation is such as will yield to the application of a few leeches and the exhibition of emetics; but it is of great use likewise to clear out the bowels by calomel at the same time, provided the inflammation is severe, and to give it steadily in small and repeated doses. The inflammation is frequently not so severe but that an emetic every day, or night and morning, will be found sufficient for all the purposes of remedying the bronchitis; still I would not trust to it in severe cases. The warm-bath, too, in this, as in most diseases of children, is of essential service. It is thought by some that the friction of tartar-emetic ointment over the chest is more useful than the application of blisters. I rather feel disposed to think that is the case, and that blisters are not of very great utility in the affection.

You will find it of very great importance not to allow children to overload the stomach; for after meals the cough is generally much more troublesome than before. The food should be, of course, when there is any inflammation, exceedingly light, affording scarcely any nourishment, and the patient should not be allowed to distend the stomach with liquids. During the whole period of the disease, even when the inflammation is gone, you will find it of use to let the food which is given be very compendious—not to be bulky. It is also of great use in the disease to prevent children from moving about a great deal, for running will frequently excite the cough; and it is also of great use to keep the child quiet mentally, for a fit of passion will bring on a violent cough. The bronchitis will sometimes continue for a great length of time. The breathing will be difficult for some weeks—there will be more or less of feverishness, and the child will waste away; but by the steady employment of antiphlogistic regimen, with a moderately open state of the bowels, many cases will do exceedingly well, notwithstanding the bronchitis may

continue, though not in a violent degree, for some time.

As it respects the Spasmodic Condition.—Next to the employment of emetics, you will find narcotics of very considerable use. Emetics will not cure the disease, because there is, in many cases, violent inflammation, and you must treat that in the usual way; but there is hardly a case of hooping-cough that will not be much mitigated by the continued use of emetics, and, in the first instance, a large number of cases may be trusted to it and the administration of narcotics. Prussic acid is very useful in this complaint; not in subduing inflammation, but in subduing the tendency to cough. You may give it to the youngest child, but of course it should be in a small quantity: if the child be young, you may put one minim to one or two ounces of almond emulsion; one tea-spoonful of which will sometimes be found as much as is proper. This is one of the most convenient modes of exhibiting it; and from the sixteenth to the fourth of a minim may be given three or four times a day. After the disease has lasted some time, you will find opium more or less useful, given in a small quantity. Dover's powder is one of the best forms. The extract of conium and hyoscyamus may be given in small doses, rubbed up in mixtures or emulsions; but I think prussic acid is one of the best things. It will not cure the disease; it has no specific power over it, more than any other narcotic, but it does remedy spasmodic irritation of the air passages exceedingly well, and very often better than other narcotics. After a certain time has elapsed, and no bronchitis exists, or so slight a degree of it that it requires no inflammatory treatment, but there is rather debility and irritation of the air passages than any thing else, tonics may be given; and various metallic tonics have frequently been employed. I do not know that any one is so good as iron; it seems to me to be the best we have. The sulphate is a form in which the medicine may be given very conveniently to children, dissolved in various mixture; and as they are fond of sweet things, the carbon may be very easily given them, mixed with treacle. I am not aware that it exerts a particular power over the cough, but, when the disease has existed some time, you will find such remedies very useful.

Some persons place a great reliance upon friction—some, external application; and narcotics are frequently introduced into it. I believe that a very good remedy is a quack medicine, called Roche's embrocation. Any stimulant not sufficient to abate the cuticle and produce inflamma-

tion, if it have united with it a quantity of opium, you will find exceedingly serviceable. Friction along the spine is particularly recommended. After a time, there can be no doubt of the use of the cold shower-bath; but one of the best things is change of air: every old woman says so, and I believe they are perfectly right. I have known (and so every one must have done) many cases where the cough continued in spite of all the medicines that could be given, and all the physicians that could prescribe them, till the residence was changed, and then the cough speedily diminished. This will not do good at the beginning; is only when the disease has existed some time, and is disposed to cease, that you find a change of air will cause it to disappear better than any thing else. The inhalation of far fumes has been recommended; but as these are acrid, it would be a wrong practice during the inflammatory stage, but when the disease becomes merely spasmodic they may be of use. The mode of employing the tar is to put it in a pipkin in the room, and let the fumes ascend so as to impregnate the air. In doing this, great care should be taken that the fumes are not too strong, or they will cause irritation, instead of subduing it; but it is a remedy that is of great use. I dare say chlorine, used about the room in the same way, would be beneficial; but great care is required not to use these things to the degree of producing irritation.

This is a very troublesome disease to treat. You may save life by subduing inflammation, but with regard to removing the complaint you may find yourself very much baffled. Much good, however, may be done, with respect to the spasmodic part of the affection, by good management—giving light food, and a very moderate exhibition of narcotics; but above all, prussic acid: its exhibition is not very satisfactory, though I am persuaded it is more satisfactory than that of any other narcotic.

SPASMODIC COUGH.

There is a cough which you every now and then see, not hooping-cough, but what may be termed *spasmodic cough*.

This affection is, perhaps, united with a degree of inflammation, or perhaps not; but if it be united with inflammation, it is out of all proportion to it. I believe this is what is meant by spasmodic cough. I have seen a few instances of a most violent cough, tearing persons in pieces, like hooping cough, but still it was not hooping cough; and it occurred in adults.

Treatment.—In this disease, I know that iron is by far the best remedy; I have cured every case which I have seen of it

by the exhibition of the carbonate of iron. In many of these cases there is no indication for bleeding, yet, if the patient be robust, it may be expedient to bleed in the first instance; but I have always treated such cases with the carbonate of iron, and with great success. In every case where the cough is out of proportion to the inflammation, or there is an organic state (even consumption), you will find iron to be the best remedy. Many cases attended by cough and expectoration, which have been mistaken for phthisis, have given way to this remedy.

NERVOUS COUGH.

I have now and then seen a very extraordinary cough in young women. All very extraordinary cases, independent of organic disease, are to be seen in young women. Cases are continually seen in young women, of so extraordinary a nature, that you would not believe in their accuracy, if you merely read them in books. I recollect very well seeing a young lady, single,—these cases almost all occur in single ladies,—who complained, that every time she inspired she coughed, night and day. She breathed slowly, but when the time came for expiration she coughed; but nothing was spit up, and on listening to the chest there was nothing preternatural to be heard. She had coughed in that way for months. At first it was quiet when she slept, but when I saw her it would not allow her to sleep. I did her no good, and what became of her I did not hear. It was the most extraordinary case I ever saw. She took the inspirations slowly, but when the time came for her to expire it was a violent cough. I have no doubt but that it was a nervous cough; that it did not depend upon any inflammatory or organic disease, and that it would cease entirely of itself in the most sudden manner. Occasionally females will have a barking cough; sometimes a violent spasmodic cough, such as I have now described, only modified in various ways, so that they will make curious sounds—shrieking,—all sorts of strange noises—unattended by organic disease, apparently arising from a mere nervous derangement of the parts. The nature of these affections altogether I have not been able to ascertain.

ORGANIC DISEASES OF THE LUNGS.

PHTHISIS PULMONALIS.

The first organic disease which I shall mention—one in which unfortunately we can do little or no good, and which causes more destruction in this country than any other affection whatever—is consumption. I shall commence, not by describing the symptoms, but the changes of structure which take place in the lung itself.

Etymology.—This disease is called in common language *consumption*, or *pulmonary consumption*; and in medical language *phthisis pulmonalis*, or simply *phthisis*, *pulmonalis* being understood. The word is derived from *φθίω* and *πνεύμων*.

Definition.—This disease is apparently of a scrofulous nature; the substance which is deposited is precisely that which takes place in parts when we say they labour under scrofula. Some have made varieties in phthisis, as being tubercular or not; but by phthisis is now meant, not an ulceration of the lung, but a scrofulous disease of the lung, which may produce ulceration, and which will produce ulceration, if it continue long enough. But ulceration not connected with this disease is not called consumption. An abscess may be formed from common inflammation, rare as it is; but that is not called phthisis—it would be called simply an abscess in the lungs, or *emica*. By phthisis is meant a deposition of a scrofulous substance in the lung, and all the organic changes to which its presence, or the state which produces its presence, give rise.

Mode in which the deposition takes place.—The deposition, in this disease, takes place in minute granules, which are greyish, semi-transparent, and pretty firm, lying close to each other over a certain space in the substance of the lungs. Although at first they lie distinct from each other, yet they are close; they increase in size, and they likewise increase in number; and as they increase in this twofold manner they of course approximate; less space exists between them; they coalesce, and form a mass. When they increase in size and number they possess less semi-transparency—they become opaque and yellow. This change is first observed either at the centre or on some part of the surface; and from the point at which it commences it gradually pervades the whole tubercle, as it is called. When they are so few that they increase considerably, each tubercle seldom exceeds the size of an almond; but the masses produced by the aggregation may be very large. I have often seen the whole of one lobe of the lung, and once I saw the whole of one lung, converted into a solid tubercular mass. It is right, however, to mention, that Laennec conceives that the tubercular deposition in such a case as this, where the whole lung or a lobe has become a tubercular mass, has taken place in a diffused manner; that there has not been a formation of distinct separate tubercles, but the substance was diffused in the texture of the lung; and he calls this mode of deposition *tubercular infiltration*. Whether he is right or not I do not pretend to say.

Shape of the Tubercles, and the situations in

which they occur.—The shape of the tubercles is round and rather oval; and this might incline us to suspect that their situation is the air-cells. That they may be formed within the air-passages is proved by the dissection of glandered horses by Dupuytren and Andral, in which the bronchial tubes were filled with granules, mixed with pus and tubercular substance. Hence it is clear that these substances may be found in the air-passages; and Andral says, that he also found a tubercular mass in the minute twigs of the bronchiæ, where no ulceration existed; of course, therefore, the deposit may be formed in the air cells. Many have said that this deposition takes place in the cellular membrane of the lungs; but when we consider its situation, and consider that it is found in the minute bronchial twigs, and not leading to ulceration, it is probable that it is formed in the air-cells. Cruveilhier says, that, after injecting mercury into the bronchiæ of a living animal, he found each globule of the metal surrounded by a concrete substance, formed of white granules, in various parts of the lungs. By injecting the mercury into the bronchiæ it only reached the air-cells, and he afterwards found granules, formed of tubercular substance, around the globules of mercury. Still it is to be remembered that a similar effect is produced in the cellular membrane by injecting mercury into an artery, and that flakes, precisely similar to those in the lungs, are seen in the spleen, and in the cellular membrane of various parts. I will not therefore take upon myself to pronounce whether the tubercles exist in the one or the other. They may exist in both; but there are arguments on both sides.

Softening of the Tubercles.—After a longer or shorter time the tubercular mass softens, and generally first in the centre, and the greater part becomes a fluid resembling pus, particles of the original solid and friable deposit being seen in the midst of it. The lining membrane, and sometimes indeed the two membranes, which are continually found around the deposition, likewise secrete pus. Long after the tubercle is gone, the membrane which surrounds it continues to secrete pus, and the cavity enlarges by ulceration. The openings of the bronchiæ, and the bronchial branches—which had been lost by the deposit surrounding them, blocking them up, compressing them, and causing them to ulcerate—are seen opening into the cavity of the abscess on all sides. Bands of pulmonary substance, and blood-vessels, shrunk and obliterated, are seen leading across the cavity, with tubercular deposit upon them, while a great number of blood-vessels are completely obliterated, and run flattened along the sides.

Tubercles usually commence at the superior part of the Lungs.—While some tubercles are advanced to this degree in one part, you will find others less advanced, and others again exceedingly minute—having been recently formed—both at a distance and in the neighbourhood. You will see them in all degrees, in all states, in the same lung; but it is an established fact, that in by far the majority of instances the greatest deviations from a healthy structure exist at the superior part of the lungs, and the first tubercles are, in the greater number of instances, deposited there. The reason why there is the greatest devastation at the upper part of the lung, is because the tubercles are first deposited there. In proportion to the duration of the tubercle, in general, is the change it has undergone; and if tubercles, therefore, be deposited in the upper part first, you will expect the third stage to be arrived at there sooner than at the other parts.

Probable reason of it.—The reason of the tubercles being first deposited in the superior part is not known, unless it be that the superior part of the chest is more exposed to the vicissitudes of temperature than other parts. It certainly is a fact, with respect both to males and females, that the upper part of the lungs is less covered by dress than the lower. In ladies, and in women of all kinds, the neck is bare, and so is the upper part of the chest; and with regard to ourselves, we have the breast more open than we are below, excepting since the close square waistcoats have come into fashion; but whether this will explain the circumstance I will not pretend to say.

Differences of opinion as to which Lung is most affected.—Some have made observations upon which lung is most affected with tubercles; Laennec says the right, but the majority of authors say the left. I have never made any observations on the matter; but as Laennec says the right, and the majority of authors say the left, I suppose that one side is as much subject to them as the other.

Condition of the intervening portions of the Lung.—The intervening portions of the lung, dividing the tubercular deposition, is frequently turgid with blood, and with a bloody serous fluid, and sometimes indurated, and either red or grey. The substance between the tubercles is by no means always healthy, but is generally in the condition I have now stated. The bronchial membrane, if you slit it up, is frequently found red, and evidently smeared with a far greater quantity of mucus than in health. Thus there is evidently peripneumonia, inflammation of the substance of the lungs, in many cases, and likewise bronchitis. There can be no doubt at all, I think, that by far the greater quantity of

expectoration in phthisis is derived from the bronchial membrane; a much larger quantity is furnished by it, I am convinced, than by the abscess; and the fluid secreted by the bronchial membrane is, as in common bronchitis, of all degrees of consistency, and of all degrees of quality.

Morbid anatomy pointed out by English physicians prior to Laennec.—Now, admirably as the morbid anatomy of phthisis has been investigated by the French, I am bound to do justice on this subject to one of our own countrymen, as I formerly did, on the subject of enlargement of the air-cells, to Sir John Floyer, and Dr. Baillie, a truly eminent physician of the last generation. In the Medical Communications you will find a very admirable paper on the morbid anatomy of phthisis, by Dr. Stark, who was a very clever young man, and fell a victim to his ardour in investigating morbid anatomy. Dr. Stark, nearly fifty years ago, pointed out that phthisis was essentially a tubercular affection—a fact which, though known to Hippocrates, had been passed over by almost every other ancient writer, Greek, Roman, and Arabian, and by many of the moderns. Sydenham himself considered tubercles and abscess as rather the effect of disease than the actual disease itself. Boerhaave was not aware of the subject. Dr. Stark established that this was a tubercular disease, and in his paper traced the tubercles from their original minuteness and solidity to their enlarged and softened state. He asserted that the chief seat of the affection was the superior and posterior part of the lungs, and particularly, he says, the left lung; agreeing therefore with a great number of writers, in opposition to Laennec. He stated that the bronchial ramifications were never obstructed nor obliterated, but opened into the cavity just as I have shewn you in the drawings; but that the blood-vessels suddenly became constricted near the orifice, and even obstructed by a coagulum, so that an injection would not pass into the abscess from the large blood-vessels, nor flow into the blood-vessels around the abscess. He found that the injection rendered the parts quite hard, so that parts which appeared firm before, became soft by contrast. He also mentioned, that the parts unaffected by the tubercles, but immediately around them, are generally red and firm; so that he found, between the effects of the tubercles and this induration, that about one-quarter only of the lungs, in extreme cases of phthisis, remained fit for duty. He ascertained that the tubercles generally have a capsule, and that adhesions of the costal and pulmonary pleura generally exist where an abscess is within. You will find, when you open persons who have died of phthisis, and

when the tubercles exist near the surface, especially if they be softened down, that there are adhesions on the outside of the surface of the lung, attaching it to the pleura. This is a provision of nature to prevent the escape of the contents of the abscess into the cavity of the membrane. The care taken by nature to prevent sudden and speedy death, which would otherwise take place, were the blood-vessels not filled up by a coagulum, and flattened down upon the sides, and the equal care taken to prevent sudden death from inflammation of the pleura, occasioned by the escape of pus from any of these abscesses, is certainly very striking; but both circumstances were pointed out by Dr. Stark long ago. The French are not aware of his existence, having till of late read so little of our English literature.

Now the symptoms of phthisis vary, of course, according to the progression of these tubercles,—both the general symptoms, and those which are to be learned by the ear.

When the tubercles are only in a solid state, and are not united together into groups, we can learn nothing of their existence from the ear; we can only presume their existence from the general state of the patient, and therefore cannot be sure that tubercles are formed. When they are sufficiently numerous to constitute groups, then, by striking that part of the chest, we hear a different sound from that which is audible when nothing but air is present. You must also suppose, that when the part is softened again, and a cavity is produced, various other sounds will be heard; the part will sound different from what it would were there no cavity at all, no unnatural state of the parts, but where the air enters a healthy part and leaves it again. From what I have said respecting the morbid anatomy, you will see clearly the reason for the different symptoms I shall have to detail. You will perceive that there must be more or less pain, cough, expectoration, and at last hectic; and you will see that the sounds in the chest must all perfectly correspond.

ON THE LATE INFLUENZA.

To the Editor of the Medical Gazette.

SIR,

THE passing features of disease are quickly lost and forgotten, if we do not pause and depict their aspect while yet they are present. "He who has not made the experiment, or who is not ac-

customed to require rigorous accuracy from himself, will scarcely believe how much a few hours take from certainty of knowledge and distinctness of imagery; how the succession of objects will be broken; how separate parts will be confused; and how many particular features and discriminations will be compressed and conglobated into one gross and general idea."—*Dr. Johnson, Western Isles, &c. Inch Kenneth.* The following sketch of the influenza, so lately prevalent in London, has been drawn with a rapid pencil from a distinct survey of many cases; and a characteristic outline of the disease is presented, as it appeared to one within the circuit of his own recognition.

In the middle of the month of March several persons were attacked with the affections of the bronchia and larynx, common in the spring of the year; but it was not till the 6th of April that the influenza developed its pathognomonic character, and within the city started up widely on a sudden, manifesting itself in three different forms. Each of these forms arose in succession, the active preceding the passive; and thus it happened:—

1. *Bronchitis*, with acute fever and keen arterial action, which presented itself in single cases towards the end of the month of March, and in the beginning of April. It yielded to the ordinary antiphlogistic treatment, and ended in a copious pituitous expectoration.

2. *A catarrh* of all the air-passages, announced by sneezing, heaviness of the forehead, suffusion of the eyes, running at the nose, and a teasing cough. There were fugitive pains along all the great muscles of the limbs; pain of the hypochondria and loins, and nape of the neck. Perspiration and soreness pervaded the skin; but the perspiration was not critical. The bowels were naturally relieved, the tongue was clean, but the urine was scanty. In healthy persons this attack lasted from three to six days, and yielded to salines, nephritics, rest, abstinence, and sudorifics.

3. *Adynamic catarrh*, announced, like the former, by sneezing, and the usual symptoms of a common cold, but distinguished by deep nervous depression and a subacute fever, running on in some instances to twenty-one days. The tongue was foul and loaded; and there was nausea, a complete loss of taste

and appetite and smell, a pale languid countenance, torpor of the bowels, præcordial distention, and a deficiency of bile. In some cases there was a sudden and very marked prostration of all the vital powers. The sleep was broken, and interrupted with frightful and fantastic dreams; the cellular tissue was lax, and the skin humid and universally sore; the urine was scanty, high-coloured, and turbid. In this form of the disease the thorax was internally sore, with an incessant cough, and a teasing glutinous expectoration; and occasionally, by fits and starts, there would be a fixed pain in the head or abdomen, simulating inflammation; the pulse being at the same time quick, and often accelerated. The patient was cast back on his bed, and appeared alarmed at his own situation.

This form of the influenza obeyed no simple febrifuge, but seemed to run a certain course, and then expire of itself, leaving a very characteristic lassitude, so as to depress the patient greatly. It was aggravated by bleeding and active antiphlogistic treatment; it was alleviated by mild purgations of rhubarb, and colocynth and mercury. But the chief means of relief was by acting on the kidneys, and causing a copious flow of urine. The soreness at the chest might be removed by a blister; and as soon as the febrile condition had passed away, the quinine was serviceable. It was always proper to impose abstinence, and absolute rest under the bed-clothes; but all patients were not submissive.

The muscular languor continued for some time after the outward restoration to health and vigour of aspect had apparently returned, and the patient was still reminded of his weakness by a lurking pain which tarried in the loins. The expectoration became chronic, plentiful, and inconvenient; the appetite might fade, the stomach and bowels falter, and a relapse occasionally ensue. The animal spirits drooped; and some invalids felt and confessed an unaccountable sense of woe.

And so much for the three forms of this malady.

Under the influence of this epidemic, asthmatic old people became gradually ill, and the medical man's attention was attracted at first to the stomach. There was vomiting of all the ingesta; pains in the hypochondria and shoulder-blades

and loins; a rapid pulse, often irregular; costive bowels; and restlessness. Gradually the respiration became high and laborious; the breath wheezing audibly; a stifling cough being incessant; and the air tubes becoming choked up with froth and a tough mucus. The patient fixed his hands and shoulders, and assumed various erect or reclining attitudes, always indicative of the greatest uneasiness. The urine was diminished, or entirely suppressed; the lips darkened; the countenance expressed alarm and anguish. The pulse in some was quick, large, and bounding; in others, rapid, little, and irregular. The skin was hot and dry, the tongue clammy, the thirst great, and the appetite gone; and so the patient might die suffocated.

The disease seemed to have its seat in the air tubes, the smaller ramifications of which were filled with a tough yellow phlegm, causing an incessant short cough, so as to clear them for the permeation of air, and the indispensable oxygenation of the blood. Here lay the disease:—1, In tough phlegm, which could be thrown off only by coughing; 2, in an imperfect and impeded oxygenation of the blood. The liver was always deranged, either as a sequence or a cause.

The object of treatment was—1, To give the lungs less work to do; therefore to bleed once. 2, To relieve the lungs by external irritants—by blisters. 3, To loosen the phlegm by warm expectorants; and 4, To act on the bowels, kidneys, and skin.

As far as my experience has gone, any treatment was fallacious. One bleeding from the arm was beneficial, but it could not be repeated; for though the blood might be both cupped and bled, yet the crassamentum was weak, and the serum abundant. Diffusive stimulants, and generous food when it could be taken, were more useful than depressants; and the difficulty seemed to lie in making the kidneys act efficiently. Vomiting was unfavourable; but a spontaneous purging seemed to be beneficial and decisive. The restlessness and vigilance could be opposed by opium only towards convalescence.

These patients might linger for the space of two or three weeks, and then get up well; or they might die in the same number of days.

Children of ten months old were also afflicted with pulmonary disease about this same period. Now their symptoms were those of pneumonia notha, and they looked like little old persons labouring under asthma. Leeches, ipecacuan, and mercury specifically, killed them; but relief seemed to be procured by mild doses of rhubarb, with half-grain doses of calomel as a purge, and a combination of oxymel of squills with the acetate of ammonia. A bland milk food was the best. Many died.

And so much for the influenza, manifested in its three forms, and in its particular modes of attack upon the old and the young.

The disease was ushered into London during the prevalence of a bleak wind and a cold vernal atmosphere, succeeding to a long, warm, moist winter. Storms of hail, snow, sleet, thunder, and rain, from dark fragments of clouds, were alternated only by currents of gelid air and harsh squalls from the north and north-east. Under these coarse rude flaws of heaven, the pulmonary organs of man, so susceptible of atmospheric changes, were excited and parched, or moistened and depressed, and the whole surface of the skin must have suffered universally in its functions. Those persons were the least liable to the influenza who were the most exposed to the outward changes of the weather; and those had it the worst who were irregularly exposed, as servants and kitchen-maids. The valetudinarian, the epicurean, and the profligate, seemed to fall readily under the distemper; and it was both curious and interesting to remark, in the mingled population of this immense city, when all were equally exposed to the same evil, the patience of the poor and the impatience of the rich. Disease may be modified and aggravated by any native or acquired irritability of temperament; and the sudden and unexpected accumulation of wealth often inflicts upon its surprised possessor a restlessness of spirit which, in animated nature, is the attribute only of birds and children. The patience of the poor is founded upon hope: they anticipate death as a refuge, a port, a harbour of safety; they foresee in the end of their days the only certainty in life. But the offensive intrusion of illness sullies the furniture of a handsome apartment, and "death is bitter to a man in the midst

of his possessions." "*Un malade dégouté,*" says Voltaire, speaking of happiness in prosperity, "*ne mange rien d'un grand festin préparé pour lui.*"—(*Articles de Littérature très intéressans.*) He who is engaged in the active pursuits of merchandize and money, or who exhausts his intellect in schemes of worldly parade and ostentation, brooks not the imperative restraints of sickness and pain, and seems astonished that his will no longer commands the servile functions of his limbs. Pride, proper to man, and fostered in polite society, may be checked by adversity, but can be extinguished only by disease, and the visible approach or vicinity of death. The physician beholds the commonalty of human nature, and hears the same words and the same phrases, expressive of the same sensations, as if the rich and the poor, the foolish and the wise, had previously met by concert, and agreed to speak the same language in their separate habitations. But as soon as health is again confirmed, the distinctions of wealth, rank, and intellect, become again paramount, and all equally defer the end of life, the certainty of which is equally unacceptable to all. At length the canopy of clouds was withdrawn, and the summer sun shone brightly as the disease faded.

I am, sir,

Your obedient servant,

JAMES ANSLEY HINGESTON.

1, Finsbury Place South,

ON THE

BANDAGE IN PARTURITION.

BY C. WALLER, M.D.

Consulting Accoucheur to the London and South-
wark Midwifery Institution.

To the Editor of the *Medical Gazette*.

SIR,

I WAS not a little surprised, on looking over your No. for May 4, to find the following remarks, from Mr. Allen, of York, respecting the application of a bandage around the abdomen during parturition:—

"In consulting the most approved writers on midwifery, I have been surprised to find no allusion to the use of

the bandage during parturition, except in Ingleby on Uterine Hæmorrhage. Many have strongly advocated its application *after* delivery, as a means of arresting hæmorrhage, by exciting contraction of the uterus; yet even for this practice I am not aware that any have recommended its application previous to the birth of the child and secundines, though on reflection it must be evident, that, to render it effectual as a preventive, it should be used before the uterus is evacuated, to excite due contraction, and to prevent relaxation."

From the period at which I became a teacher, (now eight years since,) I have constantly endeavoured to impress upon the minds of my pupils the urgent necessity of making pressure upon the abdomen before the birth of the infant. In the first edition of my "Elements of Practical Midwifery," published in 1829, the application of this bandage is described as constituting one of the duties of the accoucheur.

This small volume, however, having been written expressly for students, in all probability never found its way into the hands of Mr. Allen; but when he says he has consulted the most approved writers on midwifery, it seems strange that the venerable Denman should have been overlooked. In that author's "Introduction to Midwifery," the seventh edition of which was edited by myself, and published in the early part of last year, my own opinions regarding the bandage are thus expressed:—

"When the second stage of labour has commenced, considerable advantage may be derived from the application of a belt or bandage around the abdomen, furnished with a pad which is to be placed over the uterine region. This belt should be furnished with straps and buckles, so that it may be progressively tightened, as the abdomen diminishes in size from the descent of the child. By this continued pressure upon the uterus, a slight degree of stimulus is communicated, which encourages the organ to continue its contractions, and thus tends, in a very material degree, to prevent the occurrence of hæmorrhage afterwards. Independently of this effect, it also prevents that distressing feeling of faintness which is so apt to occur when a great degree of pressure is suddenly removed from the larger blood-vessels. This fact is well known to operating surgeons, who invariably apply a roller

of some kind round a patient's body, previously to performing the operation of paracentesis abdominis. By increasing the pressure during and after the birth of the child's head, and by retarding rather than accelerating the expulsion of the body and lower extremities, the uterus is made to act with increased vigour, and a favourable expulsion of the placenta will be generally ensured."—Page 205.

I shall feel obliged by your insertion of the above, for with the strong opinion I entertain of the propriety of the plan, I cannot but consider it to be the bounden duty of every obstetric teacher earnestly to recommend it to his pupils.

Bartholomew-Close,
May 9, 1833.

APERTURES IN THE UTERINE VEINS.

To the Editor of the Medical Gazette.

SIR,

IN the communication which I last addressed to you, I brought to your notice the work of Dr. R. W. Johnson; in which the existence of lateral apertures in the sides of the large veins of the uterus—the original discovery of which has been ascribed to Dr. R. Lee—had been distinctly announced. In looking further into the subject, I find that similar opinions have been entertained by others. I would now, in the same spirit of inquiry and axiety for truth, direct your attention to some of those authors who, in this country, or in an English garb, have described, as natural openings in the large veins or sinuses, those apertures upon the inner surface of the uterus, which, with little or no preparation, may be distinctly recognized at all, but more especially at the more advanced, periods of gestation. That these writers should have escaped the indefatigable industry which Dr. R. Lee has generally manifested in his writings, may (and certainly does) appear extraordinary; but the omission by no means implies a want of literary integrity. The charge of plagiarism involves such moral turpitude, that, without the most direct and unequivocal evidence, it ought not to be advanced; and in well-regulated minds, can, under such circumstances, only create disgust. That, however, Dr. R. Lee has

not noticed these authors, is a fact for which I can only account by his habits and taste, as all his essays manifestly prove, directing him to the study of foreign, almost to the exclusion of British authors, or by the bias of preconceived opinions leading him to examine only detached portions of the writings of those who have addressed themselves to the precise point which were the immediate objects of his researches. Upon no other principles can I reconcile, with the candour and love of truth which commonly characterize the literary productions of Dr. R. Lee, his recent statement in the *Lancet*, that "no writer in this country, or on the continent," as far as he had been able to ascertain, "before the publication of his paper in the *Philosophical Transactions*, had described these great openings in the lining membrane of the uterus which are closed by the decidua during pregnancy, and by which, after the removal of the placenta, a free communication is established between the cavity of the organ and the uterine sinuses containing the maternal blood;"—and more especially that he should have failed to notice, that, in the very paper which he has quoted for another purpose, they were distinctly so described. Dr. R. Lee is, indeed, quite right when he represents the opinion of Roederer to be that they were the result of laceration. This author, however, seems to have had no definite or clear ideas as to the precise part or texture thus subjected to laceration; for whilst, in his "explanation of the plate," he refers to these apertures as the result simply of the tearing of the inner membrane of the uterus, which, as it is now decidua rather than the mucous lining, would leave us to conclude that the holes in the veins were natural, and that they penetrated the proper mucous membrane, he yet, in another passage, quoted also by Dr. R. Lee, describes the laceration not only as existing in this "tenuior membrana uteri interior," but also in the sides, "mollibus parietibus," of the veins themselves. This obscurity of expression can only lead to the conclusion that the meaning of Roederer was doubtful: he saw the holes, but was puzzled to explain them. But Dr. Donald Monro, to whose experiment, in the "Physical and Literary Essays," &c. Dr. R. Lee has alluded, in proof of the occurrence of laceration and extravasation in the

decidua, has, in the paper referred to, minutely described them as natural apertures. He says (p. 412), "most of the apertures called sinuses were full of green injection*, and some of them had a very little of the vernilion† in them. *The internal membrane of the uterus was extended over part of each of their orifices, and these formed a sort of valve.* Some of these orifices were so large as to have allowed one's little finger to have been put into them, whilst others were so small as scarce to admit the point of a probe, and they were of all the different sizes between them." These appearances he has illustrated by an engraving, much resembling another to which I shall again have occasion to advert, in which he represents the inner membrane of the uterus, where the placenta had been attached, as completely riddled, like a cullender, by these numerous valvular openings in the veins. He has given also three other original engravings, representing detached portions of the uterus, with these sinuses opening upon their surface, and one other, copied from Albinus, in illustration of the same subject.

In "the additional observations upon gravid uteri," appended to the paper last mentioned, from the pen of Dr. Alexander Monro, this eminent anatomist has not only described these openings as natural apertures, and pointed out what he considered to be their precise situation—namely, IN THE SIDES of the veins or sinuses—but he has moreover added, and endeavoured to prove by experiment, that the canals to which they lead are supplied with blood by lateral branches of the spermatic arteries, which penetrate the coats of the sinuses. "The sinuses," he says (p. 430), "are seen, without any previous dissection, upon the inner surface of the uterus, chiefly where the placenta has been fixed; for there are but few of them, and these very small, in any part of it. Their sides are membranous; that next the cavity of the womb being in each very thin, with a large orifice in it. *They can be readily distended by blowing air, or injecting a liquor, into the veins; or they may be filled from the arteries, though with much greater difficulty, as happened in our injection; when stretched, they appear of a spher-*

* That thrown into the veins.

† That thrown into the arteries.

roidal shape, and the diameter of their orifices being less than that of their cavities, we may give them the name of *sinuses*." After considerable difficulty, he at length succeeded also in tracing the arteries into these canals; a discovery which he thus briefly announces:—"At length, near to the edge where they," *the sinuses*, "were not so frequent, I was lucky enough to discover with certainty several orifices of arteries, some of which were of a considerable diameter, opening directly into the sinuses; and since none of the anatomists have painted or described these openings, though in the imaginary structure of the sinuses they are supposed, I have caused a few of the more distinct to be represented in Tab. VII."*

Again: in the Edinburgh Medical Essays and Observations, vol. ii. p. 754, we find Professor Alexander Monro describing these holes as natural apertures, leading to sinuses *into which lateral branches of arteries enter*, and which, existing at all times, are distended with blood in the time of the menses, when their orifices also are enlarged, and are so "distended and enlarged during pregnancy, that the orifices of these canals are large enough at three or four months to receive a goose-quill;"—"and at the end of nine months, the sinuses can contain the point of the largest finger, and the canals from them can receive the little finger." The Professor refers also, in corroboration of the accuracy of his description, to Sanctörini, Obs. Anat. c. 11. § 9, and to Morgagni, Adv. Anat. iv. § 29.

Dr. Burton, too, in his New System of Midwifery, 1751, has described these sinuses, with their openings into the cavity of the uterus, as existing in the unimpregnated state, and much enlarged during pregnancy (p. 29); as having free communication with both arteries and veins (p. 19); as the source of the *menstrua* and the *lochia* (p. 20); as *the source also of uterine hæmorrhage when the placenta is detached*, in consequence of the supply of blood which these sinuses receive from the arteries (p. 20); as subject, together with their supplying arteries, to *pressure* from the contraction of the uterine fibres, "*by which too great an effusion of blood will*

be prevented," (p. 20); as capable of *inflation with air* (p. 37); and as terminating in apertures of various sizes, which he has delineated in an engraving of the interior surface of an uterus from which the placenta has been separated. This engraving bears the closest possible resemblance to that which accompanies the paper of Dr. Monro, and, bearing a prior date, may be fairly adduced as an evidence of the accuracy of both, who were obviously describing "things seen." Dr. Burton also, in his controversial letter to Smellie, further adds, "these sinuses, in the ninth month of gravitation, are so large as to admit the end of the biggest finger; and their orifices, that open into the cavity of the womb, will at the same time admit the end of the little finger," (p. 215).

Nor did these orifices escape the indefatigable Astruc; for in the translation of his work "On the Diseases of Women," Book 3, § 2, we find the interior membrane of the uterus described as "capable of distention, and perforated with a great number of little holes, imperceptible in its ordinary state, but which become very distinguishable towards the end of pregnancy."

Not, however, to enlarge more upon this subject, or to multiply quotations, I will merely add, that Dr. R. W. Johnson, as appears by my former letter, has noticed these orifices, as in some way, through their attachment to the placenta, contributing to the nourishment of the fetus; and that Dr. John Clark* has represented the sinuses as the seat of suppurative inflammation, in some of the worst forms of "child-bed fever."

It appears that Dr. R. Lee has, through inadvertency, and from not being sufficiently conversant with the medical literature of this country, erred in asserting that "no writer has described these perforations of the lining membrane of the uterus." On the contrary, it appears that many anatomists, physiologists, and obstetricians, or, in the language of Dr. Mowbray, "*Androboethogynists* of great eminence," not contenting themselves with merely alleging their existence, have described, with even more minuteness and accuracy than Dr. R. Lee himself, these

* Essays and Observations, Physical and Literary, read before a Society in Edinburgh, 1754, vol. 1.

* Practical Essays on the Management of Pregnancy and Labour, &c. 2d Edit. 1806, p. 63.

apertures, and the sinuses, or canals, to which they lead; and if they have not offered any satisfactory explanation of their nature and use, at least they have supplied us with conjectures enough upon the subject: so it has been asserted by some that they are the beginning of veins; by others that they are holes in the sides of the venous sinuses; by some they are represented as receiving from the spermatic arteries their supply of blood, which then circulates *towards*, rather than *from*, the placenta; by others, that they receive blood *from* the placenta, and carry it onwards in a continued course to the uterine veins, when that blood has done its office within the placenta. Again: they have been considered as affording nourishment to the embryo, the vessels of the placenta acting upon the maternal blood which circulates in these sinuses by a species of absorption, or "*sugillation*;" as the source whence proceed the catamenia in the unimpregnated state—uterine hæmorrhage during pregnancy and labour, and the lochia after delivery; and, lastly, it has been alleged that they are subject to suppurative inflammation, adding to the formidable character and fatal tendency of lying-in fevers.

In almost every point, then, has Dr. R. Lee been anticipated by writers of acknowledged reputation, in the description of these apertures upon the surface of the uterus leading from the cavity to the veins, or sinuses, of that organ, and in the explanation of their offices, attributes, and diseases. I may thus, indeed, deprive him of all claim to originality: in acquitting him, however, of plagiarism, it must be at the expense of impugning his industry, and familiarity with what has already been written upon the subject. In his anxiety, however, for the attainment of knowledge, he cannot fail to see that it is much more important to make out what is true than what is new; and will therefore derive even gratification from the fact, that his own views have been thus corroborated by anticipation, upon such high authority.

I am, sir,

Your obedient servant,
and constant reader,

H. HUGHSON.

London, May 6, 1833.

ANATOMY TAX—MEMORIAL TO LORD MELBOURNE.

To the Editor of the Medical Gazette.

SIR,

I ENCLOSE the copy of a memorial which I have addressed to Lord Melbourne, respecting the tax which it is proposed to levy on the profession, with the view of defraying the expenses incidental to the operation of the "anatomy bill."

My object in forwarding it to you is that the attention of the profession may be directed to the matter in question, which, as I view it, nearly concerns our common interest and character. I should have addressed this memorial to Lord Melbourne, had I conceived that, in the political tumult of the last ten days, time could sooner have been spared by his lordship for the consideration of the subject to which it relates.

I am, sir,

Your obedient servant,

A PHYSICIAN.

London, May 7, 1833.

My Lord,—Although most unwilling to take up your Lordship's time, or to obtrude myself in any way on your Lordship's notice, I still feel it my duty, as a teacher of Anatomy, to express to your Lordship my entire dissent from a proposal lately submitted to a body of Anatomical Teachers, convened in your Lordship's Office, to the effect that the Police charges incidental to the operation of the "Act for regulating Schools of Anatomy," should be defrayed by a tax on the medical profession, to be levied in the form of a Stamp Duty on the Diploma held by its individual members. I respectfully submit to your Lordship, in support of my objections to such partial and oppressive Tax, that the Bill in question was devised, not for the exclusive advantage of Anatomical Teachers, of Students in Anatomy, or of Medical Practitioners, as a class, but for the security and comfort of the public at large. The objects of the Bill, as stated in its preamble, are, the protection of Anatomy by law, and the prevention of murder, sacrilege, and other crimes hitherto resulting to society from the want of such legislative protection.

As, in the furtherance of these objects of the Bill, all classes of men are equally interested, the expenses incidental to its administration should in justice be de-

frayed by a charge common to all—by a charge, therefore, in which the Medical Profession would be included with the public, of which public its members form no inconsiderable part. It was not, I will beg of your Lordship to observe, with the concurrence of the Medical Profession, that, until within the last few months, Anatomy was stigmatized by the law of England, and that, consequently, Anatomy in England was made to depend on robbery, sacrilege, and other crimes, for its principal opportunities of study. The state of the laws relating to Anatomy in this country previous to the enactment of the recent statute, it will now be admitted, was a reproach to all classes of society, excepting only to the members of the Medical Profession, who appealed earnestly and continually, but in vain, against their folly, their barbarity, and their injustice. Surely then, my Lord, the members of the Medical Profession should, *least of all men*, be taxed for the repeal of laws by which, as a class, they were *insulted* and degraded, for the prevention of crimes which were the certain consequence of the operation of such laws, and of which the government were by them again and again forewarned.

On the same plea, indeed, with a greater shew of justice, might a Poll-Tax be demanded from Dissenters, as the price of their admission into the different municipal corporations of the realm—from Catholics, as a consideration to be paid for their eligibility to seats in Parliament—from the Jews, for the removal of the political disabilities by which they have so long been insulted and oppressed. I may further be allowed to observe to your Lordship, that as, in the *public* interest, it was *impossible* that the enormities perpetrated under the former state of the laws should be allowed to continue, the Bill for preventing their recurrence cannot be regarded in the light of a *boon* specially granted to the Medical Profession, as distinguished from the other classes of society.

Moreover, it is not for the public interest, my Lord—it would not tend to the comfort and tranquillity of the public mind, that Anatomical Teachers and Students should buy the Bill for regulating Schools of Anatomy from government—that the inspector of the Anatomical Schools should be paid by those whom he inspects. The members of the

Medical Profession *should*, and *must*, be above suspicion in this matter. By submitting to the Tax which your Lordship has thought fit to propose to them, they would appear to buy from the government a legal degradation, disgraceful only to the Legislature which imposed it, and might be supposed to admit an imputation as attaching to them crimes for which they, of all others, are least responsible; and which, in common with all men, they regard with grief, horror, and dismay. I further submit to your Lordship, that the trouble (to which in the public interest they cheerfully submit) imposed by the clauses of the Bill on Teachers of Anatomy, is considerable, and that the expenses incurred by them and by their students in Dissection, are still enormous as compared with those of the French and other Schools—that they cannot, on any principle of public justice, be considered as *gainers* by the Bill, in being released through its provisions from expenses, insults, and persecutions, which had latterly become intolerable. I do not hesitate to represent to your Lordship that it would even be impossible to withdraw the protection of the law from the study of Anatomy, and that should the Medical Profession decline payment of the tax which it is proposed to levy *exclusively* on them for the advantage of the public at large, the Government are still bound to prevent the extinction of Anatomical Science in this country, and to prevent the recurrence of the dreadful crimes by which, in the absence of all legislative protection, it must of necessity be accompanied. It is, I need not observe, the direct interest of every man afflicted with, or liable to, Disease and Accident, that Anatomy should at least be tolerated in this country; and I venture to express to your Lordship my humble opinion, that it is the duty of every Government to secure its peaceful cultivation for the benefit of all, against outrage and without crime.

I further take the liberty of calling to your Lordship's recollection a correspondence which took place between Mr. G. Lamb and myself on this subject, in the month of September 1832, when the Act first came into operation. In reply to a letter resisting the demand of an "Office Fee" of *2l. 2s. 6d.* on the Anatomical License, as unauthorized by any of the provisions of the Act,

Mr. Lamb states, from your Lordship, that "he had given directions, with a view of reducing the expense to the parties (as far as the official regulations will admit of), that any number of persons requiring a license to practise Anatomy in the same place, shall be included in the same license; and that in those cases where it may be necessary to renew any license, on account of change of residence, no fee whatever will be charged for such renewed license."

I respectfully submit to your Lordship, that by this letter a promise is virtually given from the Home Office to the members of the Medical Profession (all of whom are included in the class of Anatomists) that no sum shall be demanded from them, under pretext of the Bill, excepting this, the Office Fee of 2*l.* 2*s.* 6*d.* to be charged on the Anatomical Teacher as the price of his license. It was, I beg leave to observe, in the fear that the principle on which this demand was made might *afterwards* be extended to the great body of Anatomical Students, that I at once felt it my duty to address your Lordship on the subject.

In reference to the correspondence to which I have alluded, I cannot refrain from expressing my sincere opinion, that the exaction of a Stamp Duty on the Medical and Surgical Diploma, with the view of defraying the Police charges incidental to the Anatomical License, must be regarded as a breach of faith (however unintentional) from the Government to the Medical Profession. I respectfully urge on your Lordship's kind attention, that the sum which it is proposed to raise could, in very many instances, be ill spared by the Anatomical Student, whose means, and those of his family, are frequently exhausted by the expenses of the protracted education required from him by those who grant his Diploma. I beg, in conclusion, to direct your Lordship's attention to Clause VI. of the Act, by which it is provided, "that it shall be lawful for his Majesty to grant to every such Inspector an annual salary, not exceeding one hundred pounds, for his trouble, and to allow such a sum of money for the expenses of his office as may appear reasonable; such salaries and allowances to be charged on the consolidated fund of the United Kingdom, and to be pay-

able quarterly, and that an annual return of all such salaries and allowances shall be made to Parliament."

By this clause your Lordship will observe, that the charges incidental to the Bill are distinctly recognized as attaching, not to the Medical Profession in particular, but to the Public generally; that the Fund from which they are to be defrayed is a Public Fund, and that under the present Bill, the Government and Parliament are both directly pledged to the payment and proper disbursement of the sum thus required for an important public service; and this without any reference to the opinions, wishes, or interests, of the Medical Profession, entire, or in any of its divisions.

I have the honour to be,

My Lord,

Your Lordship's obedient servant,

* * * * *

London, May 7, 1833.

CLAIMS OF THE EDINBURGH SURGEONS

TO PRACTISE AS APOTHECARIES IN ENGLAND.

To the Editor of the Medical Gazette.

SIR,

THE natives of this country are as proverbially slow and apathetic in any matters that concern their interest, as our neighbours to the north of the Tweed are active and vigilant; and the manner in which the respective parties are proceeding at the present time, is a proof of this fact. In your last number you notice the very important alterations in the Apothecaries' Act which are contemplated by government, by which the different graduates of Scotch Universities, and the members of the Edinburgh College of Surgeons, are to have the right of practising in England as apothecaries.

I do not mean to enter into the propriety of this very strong measure, by which a person educated for one branch of the profession in one country, is to be allowed to practise another branch of the profession in another country; neither shall I dwell upon the different claim set up by the graduate, as compared with that brought forward by the Edinburgh surgeon, which may by some be considered superior, in conse-

quence of the presumed superiority of the education of the former over the surgeon and over the apothecary also; though it would seem, from the rejection of so many graduates by the Examiners of the Apothecaries' Company, that this superiority is but assumed. I cannot but express my opinion, however, that if the apothecaries of England have been so considerably elevated in public estimation by the compulsory examination established in 1815, as to make it desirable for the Scotch graduate to drop his dignity, and practise in this country as an apothecary, that I cannot see any hardship in his not being allowed to supersede and set at defiance the authority of the public body, which has, by its judicious regulations, effected this very change, because the higher character for knowledge, which he claims to himself, ought to render the examination by the Apothecaries' Company, whose laws admit him to examination, a very easy matter to him, after the superior one he has already undergone.

I wish, however, to draw your attention more especially to the Edinburgh surgeons, who were, by the proposed measure, to be also enabled to practise as apothecaries in England. I submit, sir, either that they have no claim at all to this boon, or else that the member of the English College of Surgeons (who at present has no power to practice as an apothecary in his *own* country) ought at least to have as much power granted to him as is conferred upon the member of the Edinburgh College. I cannot, certainly, understand by what rules of law or equity a foreigner is to enjoy greater privileges in England than are conferred upon an Englishman of the same rank, and character, and education.

The members of the English College of Surgeons have been repeatedly prosecuted for practising as apothecaries (see *Alison v. Haydon*, and many similar trials), and the Judges have as frequently decided against them. Either, then, the Edinburgh surgeon ought not to have his name inserted in the act as exempt from the Apothecaries' jurisdiction, or the English surgeons ought to bestir themselves to have their claims allowed also, as exempted from its operation.

You will observe, sir, I have expressed no opinion as to the propriety of

such a regulation in either case, but only expressed my conviction as to the equal rights of both parties; especially as I know, by the experience of many persons who have undergone both examinations, that the ordeal before the London Examiners is often much more trying than that before the Edinburgh College. For my own part, however, I can see no reason for the contemplated alterations in either case. Let the two bodies of surgeons practise as surgeons; or if they are desirous of combining their own profession with another, let them shew their fitness to do so, by undergoing such proofs of their knowledge as the legislature has considered right and proper, and the working of which, on the whole, has been found productive of public good, by all parties except these new and foreign claimants, with whose rights and privileges in Scotland the English apothecaries never interfere.

You may perhaps recollect that a temporary act was passed for one year in 1825, to amend the Apothecaries' act of 1815, which gave the power, perhaps very properly, to the "surgeons and assistant-surgeons in his Majesty's navy, to the surgeons or assistant-surgeons, or apothecaries, in his Majesty's army, and to the surgeons and assistant-surgeons in the East India Company's service, to practise as apothecaries in any part of England or Wales, without undergoing an examination by the Company of Apothecaries. This act might be again renewed without hardship to any person, because their officers have undergone *additional examination* since they obtained the diplomas of the two Colleges of Surgeons, and by it a great number of Edinburgh graduates and surgeons, *who had proved their fitness*, would be at once allowed to settle in England, since so many of them are officers in these services."

There is also another clause in this temporary act, which might perhaps be re-enacted with advantage: it is this:—

"Whereas, many persons who served an apprenticeship of the like period (five years) to surgeons, have received a full and competent medical education to enable them to practise as apothecaries, but the said Court of Examiners *have not any power to examine* such persons; be it therefore enacted, that from and after the passing of this act, it shall and may be lawful to, and for the said Court

of Examiners, to examine such persons as to their fitness for, or qualification to act as apothecaries, who shall produce proof of having served an apprenticeship of not less than *five years* to a member of the Royal College of Surgeons in London, or to a member of the *Royal College of Surgeons in Edinburgh*, or to a member of the Royal College of Surgeons in Dublin, or to a surgeon in his Majesty's army or navy; together with proof, to the satisfaction of the said Court of Examiners, of a sufficient medical education, and of good moral conduct; in like manner as by the said act is provided with regard to persons who have served an apprenticeship of not less than five years to an apothecary."

Such a clause as this ought perhaps to satisfy all the members of the Edinburgh College of Surgeons, who are not willing to prove their own fitness by passing through the required examination, when they wish to leave their own country to practise as apothecaries in another part of the United Kingdom, to which their own laws do not extend.

I would shorten the term of apprenticeship; indeed, as the Company of Apothecaries themselves very properly wished to do, as to their own apprentices, against their own interest, when they were compelled to give way to the House of Lords.

I have the honour to be sir,

Your obedient servant,

AN ENGLISH SURGEON.

May 13, 1833.

DEFECTS IN THE APOTHECARIES' ACT—PROPOSED REMEDY.

To the Editor of the Medical Gazette.

SIR,

THE remarks in your last leading article, on the changes contemplated by government in the Apothecaries' Act of 1815, must have commanded the attention of every reader in every part of the three kingdoms. With the general spirit of those remarks I cordially concur; but you will, I am sure, excuse me for saying, that they serve only, in the language of the law, *to open the case*. Much, very much, remains behind, requiring deep and long and patient attention. Permit me, then, to throw together the first reflections of my own

mind, on a subject thus pregnant with interest to the members of the medical profession throughout the country—whether physicians, surgeons, or apothecaries, young or old, practitioners or pupils.

It has been too much the fashion of late to ground the defence of the Apothecaries' Act upon the improvements which it has effected in medical education since 1815. All that is readily conceded. But it is time to do something more than to look with complacency upon our present position compared with that of our predecessors. Eighteen years have elapsed since the Act came into operation: circumstances have a good deal changed since then; and it surely is worth considering, since the government are going to interfere, whether they may not, while they are about it, make such improvements in the Act as will benefit *this* country as well as the Scotch colleges. The general character of the Medical Gazette assures me of one thing,—that its pages will be freely opened to the advocacy of measures which tend equally to benefit the public and the profession. If it can be made to appear that changes in the Apothecaries' Act are called for by the circumstances of the times—that they will tend to conciliate parties, to lessen useless expenses, to uphold what we have got that is good, and to add to the store—to remove absurd and discreditable anomalies, and to take out of the hands of those who live by calumny their only just grounds of complaint—then am I sure of your co-operation.

The grounds on which the *first* inroad on the provisions of the Act of 1815 is based, are these. The graduates of the Scotch universities, and gentlemen holding diplomas from the Edinburgh College of Surgeons, complain, that while they are allowed to practise on the King's lieges in Scotland, and in the army and navy, and colonies, they are not permitted to practise in England until after a *second* examination. The matter, too, is made worse, by this second examination taking place before a Board composed of what the courtesy of the world denominates an *inferior* grade of practitioners. Scotch physicians and surgeons are examined (and not unfrequently rejected) by English apothecaries! This certainly sounds harsh. The Edinburgh and Glasgow doctors argue, fairly enough,—“if we are unfit

to practise in England we are equally unfit to practise in Scotland;" and the government should in strict justice take from the Scotch colleges their privilege of conferring diplomas, if they use that privilege badly, or if otherwise, make it available over the *whole empire*. Scotland is united to England by a solemn act of the legislature. A *foreign* state (France, for instance) might reasonably enough require a Scotch or English diplomatist to undergo a second examination before the lives of Frenchmen were entrusted to his care; but how can such a principle apply with any fairness to the several portions of one united kingdom? If, for the purpose of preventing imposition, and of securing the public from danger, registration in London is requisite, let the Apothecaries' Company in London admit Scotch graduates and surgeons to a diploma *ad eundem*, just as a Master of Arts of Trinity College, Dublin, is admitted to a like honour in Oxford or Cambridge, on demand. All this is fair and intelligible. Indeed it seems to me that the Scotch doctors have evidently the best of the argument; and that government think so is plain from their consenting themselves to bring in the new Act. The only wonder is, that the Scotch, who are tolerably *canny* in looking after their own interests, should have put up with the injustice so long.

It is no answer to this, to say, as I have often heard said, that the Scotch physicians and surgeons are, in some instances, found, upon *re-examination*, to be incompetent. Hundreds of men now practising in England, and practising with credit too, would, if called up before the Court of Examiners, pass a very bad re-examination,—be unable to answer one word about the chemistry of the hydriodates, and stumble, perhaps, at the very first question in anatomy. The point in dispute is, not whether the party can or cannot pass a second examination, but whether a second examination is or is not a fair thing. If a man be once declared competent, by a *recognized* authority, is it fair to put him to his trial again, merely because his patient lives in Newcastle, and not in Jedburgh? Why may we not admit the principle of CONCURRENT JURISDICTIONS? Let the Colleges of Surgeons of Edinburgh and Dublin have a concurrent jurisdiction with the Apothe-

caries' Company of London, and let the diplomas of each pass current in the several portions of the empire.

But here a second question meets us, and well worthy is it of every attention.

If we concede, as I think in fairness we must concede, the demands now made by the Scotch Colleges, why should not the College of Surgeons of London possess a similar privilege? Observe the strange anomaly in which we are now placed. The Apothecaries' Company do not, and say they cannot, by law, examine in surgery. The College of Surgeons has no authority to compel the attendance of pupils. A man therefore, as the law now stands, is prosecuted and fined, if, without a license, he gives a patient a dose of salts out of his own shop; while the very same man is legally entitled to cut off that patient's leg, or to tie his carotid artery!

Well may foreigners stare when they are told of such an anomaly in the medical police of this country. One of two things ought long ago to have been done,—either the College of Surgeons should have petitioned the Legislature to throw a legal sanction over their proceedings, and to grant them concurrent jurisdiction with the worshipful Company of Apothecaries; or the said worshipful Company should have petitioned Parliament to give them the power of examining in surgery.

It is certainly discreditably to this country, that things should have remained in their present state for eighteen long years, and absolutely impossible that this should continue many years longer. Why are not the College of Surgeons of London as active as their brethren in Edinburgh? Let them awake from their slumber, take warning from what is passing around them, and seize the golden opportunity which now offers, of recovering their legitimate share of influence over medical education in this country.

In my next communication I propose to address myself to some other defects in the Apothecaries' Act.

Until my namesake recovers from his present severe attack of trismus, permit me to subscribe myself,

Your obedient servant,

MANILLA INFERIOR.

London, May 13, 1833.

MEDICAL GAZETTE.

“Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri: potestas modo veniendi in
publicum sit, dicendi periculum non recuso.”

CICERO.

ENGLISH AND SCOTCH GENERAL PRACTITIONERS.

IN a subsequent page we give the official documents—the special messages, of the two bodies who contend which should have the better right to supply the public with general practitioners. We wish the impartial reader would peruse them attentively, and form for himself a deliberate opinion of their respective contents. For our parts, without presuming to guide the profession on particular points connected with the subject, we shall content ourselves with a few remarks on its general bearings, and consider the question, at least for the present, in its broad and chief aspect—namely, as to the effect which a decision in either way will have on the public welfare.

It might seem to be almost superfluous to observe that in every question of this sort the public interest should be attended to in preference to that of any individuals or particular set of men: yet we fear that the principle, however obvious, is too apt to be overlooked, and we more than apprehend that on the present occasion it has been rather thrown over-board by our northern brethren.

The question is not merely which system—the present, or that which is proposed to be put in its place—is calculated to supply an abler class of practitioners—though touching this point there is ample room for difference of opinion—but which, either by its direct operation, or the abuses it might lead to, would be most likely to leave the public in an unprotected state—exposed to

the malpractices of shoals of quacks and pretenders. Now it happens that both systems have been already tried, and of each some sort of judgment may be formed: that of the Society of Apothecaries has been in action during the last eighteen years; and with what vigilance those functionaries have discharged their duty during that period even their opponents must admit: while of the effects of the uncontrolled immigration of Scotch practitioners, and those who, under their banner, practised their impositions on the public, the country had woeful experience in the very circumstances which called for the Apothecaries' Act.

Thus a *primâ facie* case is made out in favour of the existing system, so far as the protection of the public is concerned: not that we mean to say that such protection is at the present moment, or has been, as complete as it ought to be; for the truth is, that even as matters have stood for years past, the encroachments of unqualified intruders have been such as to shew the inefficiency of the means adopted by the legislature for the care of the public welfare; but what we mean is, that if the Apothecaries' Act has been in some respects inadequate to the ends proposed, the contemplated changes will most likely throw open the door to truly dangerous consequences. To the injustice, then, that would accrue to the public from immature or meddlesome legislation, we are desirous at present of calling the reader's best attention; though not less obvious than this is the special injury which such legislation would inflict on a large and valuable body of the community—the general practitioners, upwards of 10,000 in number, who, having complied with the arrangements of the present system, on the faith of being allowed to pursue a respectable career, un molested by unqualified intruders, are clearly entitled, next after the commu-

nity at large, to the special protection for which they may be said to have solemnly bargained. Under the system which it is proposed to adopt as an improvement, these gentlemen will have to struggle for their subsistence with numbers of adventurers who, under the mask or pretence of Scotch qualification, will inundate the country. Nor is it possible to overlook the serious detriment with which the introduction of such a system must also affect those gentlemen, more particularly belonging to the provincial schools, who have devoted themselves to the business of education on the faith of the existing law, and whose excellent system of discipline, now matured and generally approved, must be humbled in the dust, in order to give place to the wider range of Scotch practitioners and teachers. These latter results are so obvious that it is impossible to avoid noticing them even while intent on matters of more general scope; and we will only add, that perhaps nothing can afford a stronger contrast than the cool indifference with which the English parties just alluded to, and whose interests are unquestionably at stake, sit down in passive contemplation of the incursion meditated upon them, and the stirring activity and decided purpose manifested by their adversaries in the north. But as we have said, in the consideration of these matters, the interests of particular groups concerned in the contemplated changes, must give way before the superior claims of the public good.

It was a state of things infinitely worse than is even now pretended to exist that gave rise to the present powers of the Apothecaries. The country was overrun with hordes of barbarous empirics, from whose dangerous doings the public had neither security nor protection. In such circumstances the safety of the community necessarily became an object of attention to the legis-

lature: and hence the act of 1815, which constitutes what the Scotch claimants call a "monopoly." The term may be a convenient one for our northern petitioners, and the more so as there is something invidious about the very sound of it; but if we understand aright, its meaning is simply this—that England and Wales, from time immemorial, up to a certain period, had been the free and undisputed manor of all comers, licensed sportsmen, poachers, and all; whereas it has been reserved of late years for those who have special qualifications; and certain gamekeepers have been appointed for the better preservation of the game, and for repelling the intrusion of the unqualified. These gamekeepers are the monopolists. The term, however, is used in a sense ostensibly more precise and plausible: it is complained by the Scotch reformers that the general medical practice of England is monopolized solely by those licensed by the Society of Apothecaries, and that it is unfair, nay unjust, to exclude thus from English practice gentlemen of Scotland who do not choose to submit to the regulations laid down by the existing law. They hold that to a certain extent, of course as far as will suit their purposes, things should be in common between the two countries; and that it is very hard that the Tweed should be the boundary of the general practice of Scotch graduates and diplomatists willing to settle on English ground. Such a limitation they hold to be a monopoly. On the other hand, the advocates of the Apothecaries' Act point out the imperative necessity of keeping up a restriction of the kind, for the sake of the public safety; they show the confusion to which a removal of Scotch disabilities would give rise; and without answering the charge of monopoly, in the sense in which the Scotch petitioners employ it, they content themselves with a strong

counterebargo, which we fancy the gentlemen who derive their qualifications from beyond the Tweed cannot easily get over. The Apothecaries retort upon their opponents that their demand is truly unblushing: that they (the Scotch) migrate from a country in which, by the existence of notorious and rigidly-enforced monopolies, they are prevented from practising at all in certain parts, and that they make an outcry because they cannot find in another kingdom the privileges and prerogatives which they are denied at home.

Though this may not be altogether relished as a "retort courteous," it will by many, no doubt, be considered as a *noli me tangere* sort of argument; and we confess we should not be much indisposed to estimate it in that light, did we suffer ourselves to be circumscribed by questionable and narrow views of medical polity. The complaint of monopoly, on the one hand, and the retort on the other, only shew that something that should be otherwise than it is exists on both sides. There is monopoly here, but there is a much more illiberal monopoly there. What does this mean, but that two bad things are engrafted in the medical constitution of the country—differing rather in intensity than in kind—and that both ought to be purged away? Every thing savouring of monopoly, in its odious sense, should be rooted out of the medical commonwealth; and if reform is to be introduced at all, as we trust it will, with all those legitimate and sound precautions which we have had occasion from time to time to point out, it will set things upon so enlarged and liberal a foundation as to exclude all monopolies—more especially of that pitiful sort by which the boundaries of Edinburgh and Glasgow practice are so strictly and selfishly defined.

It certainly ill becomes the Scotch diplomatists to manifest so much zeal

for reform abroad, while they tamely submit to such unreformed grievances at home. Nor do they or their advocates come before the public with a much better grace, when they proceed to attack the system of education laid down by the English Apothecaries, on the score of interested motives—or as some of them would say, of "monopoly" again—while it is a notorious fact, that among the most strenuous promoters of the scheme at present contended for by the Scotch, are the very men who not only license our northern reformers, but have a direct interest in carrying the measure, inasmuch as they are the teachers of those whom they license. On this point the Society of Apothecaries have a triumphant advantage over their opponents.

And there is another point which, we are sorry to add, would seem to indicate that the purity of the motives of our Scotch reformers is not altogether free from suspicion:—we allude to the extraordinary precipitation with which they managed to get up their new bill, and the singularly sly way in which they attempted to forward it smoothly through Parliament. The Lord Advocate did his part with a most praiseworthy speed; it is said he had the bill actually ready, with all the formalities about it complete, to be shoved on through its various stages at the first convenient moment. The arrangements were all capital; no plan could be better laid; no managers were ever more carefully chosen. One thing alone was unfortunate—that the end did not adapt itself to the means: the result has been a failure—at least for the present. We have now only, in conclusion, to recommend those whose promptitude has been frustrated, and whose energies have suffered a repulse, not to allow themselves to be betrayed into intemperance of language, or to mistake the invectives prompted by the bitter-

ness of disappointment for the reasonable acts of calm reformers. This we feel obliged to suggest, in consequence of observing in several of their printed and written documents which have recently fallen in our way, a most lamentable lack of argument connected with a very plentiful profusion of low abuse. One production from Scarborough we would instance, as equally conspicuous for its solecisms and its scurrility.

ORIGIN OF ACEPHALOCYSTS.

THE following case shews that a mechanical lesion may give to the part injured a disposition to form these parasitical productions. A girl, aged 16, of good constitution, though rather delicate, and who had not menstruated, fell while carrying a pail of water on her head, and struck the front of the thigh with so much violence that she could not rise for some moments. The part was fomented, and got so quickly well that in three days she was able to go about her usual avocations. A little swelling remained, but attracted no particular notice. This occurred in the summer of 1823. However, in June 1824, the swelling had become as large as a hen's egg, and continued to increase until, after severe exercise in the fields continued during the day, the tumor became so large and painful that the patient could neither walk nor stand. Dr. Held, of Franksbourg, by whom the case is related, was then consulted. He found an elastic tumor on the anterior part of the right thigh, and following the course of the rectus muscle. The thigh was about double the size of the other, but the skin retained its natural colour. The surgeon at first took it for a lymphatic abscess, and recommended various remedies to relieve pain and inflammation. Nevertheless, fluctuation could not be perceived; but in its place a kind of elastic trembling, like that of firm jelly. However, caustic was applied, which penetrated to the fibrous covering of the thigh, but without reaching the tumor. The ulcer thus formed was kept open till December, but still the tumefaction increased, when, at length, in February 1825, the tumor burst spontaneously: pus, mixed

with blood, flowed at first; and then, during five days, a yellowish serous fluid, with thousands of hydatids of different sizes, from a millet-seed to a hen's egg. The hydatids were spheroidal, colourless, neither adherent to each other, nor to the adjacent parts. In nine months the swelling was quite reduced, and the limb entirely restored.—*Hecker's Litterarische Annalen.*

INTERNAL USE OF CHLORINE IN NERVOUS FEVER.

DR. CLEMENS, of Frankfort, almost always commences the treatment of typhoid affections by an emetic, to which succeed gentle purgatives, (neutral salts) continued for several days; five or six evacuations being produced daily. The head is generally relieved by this; but if not, from twelve to twenty leeches are then applied to the forehead, temples, or behind the ears, with cold applications to the head, and a blister to the back of the neck. If, towards the fifth day, nervous symptoms set in, he prescribes two drachms of chlorine water in three ounces of distilled water, this mixture being taken a spoonful in the course of the day. In administering this medicine, it is necessary to avoid adding any kind of syrup, because it favours decomposition, and it is also necessary to keep the bottle covered with dark paper, and in a dark place. On the sixth day, Dr. Clemens has the patient somewhat more warmly covered, and discontinues the cold applications. During the six or seven days which follow he makes little change in the treatment, except that the dose of chlorine is gradually increased to four or six drachms daily, in three or four ounces of distilled water. Perspiration generally continues from the sixth or eighth day, and two or three stools are procured. After the fifteenth day the chlorine is changed for a light infusion of valerian, and veal or chicken soup. At the end of three weeks decoction of bark is administered, and meat allowed.—*Medizinisches Conversationsblatt*, No. XV.

CRYSTALS ON THE SURFACE OF THE COLON.

DR. EHRMANN, of Strasbourg, met with the following case lately in his clini-

cal practice. A man, 54 years of age, of lymphatic temperament, entered the hospital after having been ill during six or seven months: he was weak, emaciated, and with the aspect of labouring under disease of long standing, which was suspected to be cancerous. There was a tumor near the anus as large as the fist, hard and irregular. He had vomiting, obstinate constipation, &c. and at length died exhausted, and in the last degree of extenuation. The descending colon was found to be in a state of cancerous degeneration, which had produced constriction of the bowel. Above the part the intestine was much dilated, and the walls lined with a black substance, brilliant, and with crystals visible to the eye. These crystals were hexaedra, transparent, and insoluble in water. They were subjected to chemical analysis by Dr. Tauffeils, who gives the following details. They were not altered by a red heat; they dissolved without effervescence in muriatic acid; the oxalate of ammonia threw down a copious precipitate of oxalate of lime; and ammonia gave rise to a white precipitate, having all the characters of phosphate of lime.—*Gazette Médicale*.

SUCCESSFUL CASE OF TRANSFUSION OF BLOOD.

By DR. SCHNEEMANN, of HANNOVER.

THE subject of this case was a stout healthy woman, aged thirty, who had already had two children, and at each delivery had suffered considerably from hæmorrhage, before the removal of the placenta. On her third delivery, a violent hæmorrhage set in about two hours after the birth of the child, the placenta being still retained, in spite of the efforts of the midwife to promote its expulsion, by friction and pressure on the uterine region; she then attempted to extract it, but in vain; she therefore sent at once for Dr. S. On his arrival he found the patient in a faint, which had lasted for some time, and respiration and circulation were scarcely perceptible; the abdomen seemed pretty much enlarged, but the hæmorrhage had ceased for the time. He immediately ordered her some wine, and a tea-spoonful of tincture of cinnamon; and when she had come a little to herself, introduced his hand into

the uterus, and extracted the placenta, first removing the coagula, which had quite plugged up the entrance. The organ then contracted powerfully; which of course prevented the renewal of the hæmorrhage. The patient now got some more wine, and half a drachm of secale cornutum; the latter being thrice repeated. In consequence, she gradually recovered, so much that Dr. S. did not think it necessary to remain any longer, having been already some hours with her. Accordingly, he ordered her some laudanum, and went away. Soon afterwards, however, the husband of the patient came to him, with the intelligence, that on his wife's turning in the bed, the hæmorrhage had come on again with great violence; that when he left her she was speechless, and that he feared she would be no more before they returned. Dr. S. at once saw that the only chance of saving the poor woman was to have recourse to the transfusion of blood. Not having a proper apparatus for the purpose, he purchased a syringe with a long pipe, on his way to the patient's house, and brought two medical students with him as assistants. On their arrival, they found her with every sign of approaching dissolution: the hæmorrhage had ceased, and the uterus was larger than when he had left her. He therefore again introduced his hand into it, removed the large coagula with which it was distended, and, by pressing for a few minutes through its posterior wall on the aorta, endeavoured to determine the small quantity of blood that remained more to the heart and the brain. By this means, together with pressure on the uterus from without, the organ began to contract and resume its usual size and form: leaving it to the midwife to attend to keeping it so, he next prepared for the operation of transfusion. The husband readily offered his arm; and, after some difficulties, from the nature of the apparatus, about seven or eight ounces of blood were injected: the man then became so weak and faint that no more could be taken from him. In about half an hour after the operation, the woman began to come to; and in three hours, with the assistance of wine and other restoratives, she was wonderfully recovered. The hæmorrhage did not again return; and though she subsequently suffered greatly from inflammation of the wounded vein, in consequence of

which she had to undergo a severe salivation, she eventually regained her health and strength, a great paleness of the countenance being the only visible memorial of the danger she had escaped. —*Dublin Journal*, No. VII.

STATEMENT ON BEHALF OF THE ROYAL COLLEGE OF SURGEONS OF EDINBURGH.

THE Royal College of Surgeons of Edinburgh respectfully request attention to a petition which has recently been presented by them to the two Houses of Parliament, and of which a copy is annexed.

The object of that petition is to pray that Parliament will be pleased to modify an act passed in 1815, commonly called the Apothecaries' Act, so far at least as may enable such persons as have obtained licenses to practise Surgery and Pharmacy from the petitioners, (or from any other public body duly authorised to grant licenses of this description,) to exercise their profession in England and Wales, as well as in other parts of the United Kingdom, on a fair footing and equality with those obtaining licenses from the Society of Apothecaries in London.

In support of the prayer of this petition, the petitioners aver, and are prepared to shew,

1st, That the Charters and Acts of Parliament in their favour, empower them to superintend the education, and to ascertain the qualifications, of those desiring to be licensed to practise surgery and pharmacy.

2d, That, from the constitution of their College, they are worthy of this confidence.

3d, That those to whom they intrust the immediate duty of examining candidates for their diploma, are persons fully qualified for this duty, and perform it with great strictness, and the most perfect fairness.

4th, That the course of education prescribed by the College to those desirous to obtain their diploma, comprehending instruction in the various departments of medicine, — chemistry, materia medica, and pharmacy, anatomy and surgery, midwifery, and the practice of physic, — is well suited to prepare them to act as general medical practitioners; is, in fact, as complete as any, and more complete than most, of the courses of study prescribed by other public medical bodies who grant licenses to practise the medical profession; and, in particular, is superior in efficiency to that prescribed by the Society of Apothecaries.

5th, That their diploma is considered,

by persons well qualified to judge, as a satisfactory testimony of professional education, and that it is sought for by persons from all parts of the United Kingdom, as well as from his Majesty's Colonies.

6th, That previously to the passing of the Apothecaries' Act, in 1815, those holding the diploma of the College were accustomed to act as general medical practitioners throughout England and Wales, and, as such, obtained a considerable share of public patronage.

7th, That the power conferred by the Act of 1815, on the Society of Apothecaries, of preventing all persons from acting as *Apothecaries* in England and Wales who have not obtained their license, is tantamount to a monopoly of the general medical practice of those parts of the United Kingdom in favour of their licentiates; the demand for persons who confine themselves to the practice of physic, or of surgery, as distinct departments of the profession, being extremely limited as compared with the demand for persons practising all departments of the profession conjointly.

8th, That the Society of Apothecaries possessed no such power previously to the Act of 1815, their authority having been confined to London and its immediate vicinity, and even there not enforced.

9th, That that part of the Act which renders an apprenticeship of five years an indispensable qualification for those who are to obtain the license of the Society of Apothecaries, is highly injurious to medical education; and if acted on, according to the interpretation put upon this clause by the Society of Apothecaries, renders it impossible for any one who has received his medical education in Scotland to be admitted a licentiate of that body, and, consequently, to settle as a general medical practitioner in England or Wales.

10th, That the Act of 1815, in favour of the Society of Apothecaries, has had the effect of preventing persons from acting as general medical practitioners in England and Wales, whose certificates of qualifications were much more ample than those of their own licentiates.

The petitioners humbly submit, that the Apothecaries' Act would have imposed a great and uncalled-for hardship, even if its effect had simply been, that persons who had previously obtained a license to practise the different branches of the medical profession from a competent authority — after having passed through a sufficient course of education, undergone a sufficient examination, and paid the fees which that body might be authorised to exact — should be compelled to undergo additional examinations before the Society of Apothecaries, and pay additional fees to them, before

settling as Apothecaries in England or Wales. But this grievance would have been trifling, in comparison with that which arises from the qualification prescribed by that Act as essential to being admitted to examination before the Society of Apothecaries, namely, the having undergone an apprenticeship, with an apothecary, of five years duration. The College are convinced that this is a regulation in the highest degree injurious to medical education, however beneficial it may prove to the practising apothecary, by ensuring him a supply of persons to execute gratuitously, or even to pay a large fee for being permitted to perform, the menial details of his business.

With regard to the uses and abuses of medical apprenticeships, the College concur in the following opinions, expressed by a member of their own body, and which met with the approbation of the Commissioners for Visiting the Universities and Colleges of Scotland:—"That it may be highly advantageous for young men, entering upon the study of medicine at a regular school, to be placed under the immediate superintendence of individuals able and willing to guide them in their studies, will not be denied; but it does not seem essential towards obtaining the advantages of this superintendence, that the student should be condemned to pass a large portion of every day of a long apprenticeship in performing the menial drudgery of a general practitioner's shop, whilst all the practical skill in pharmacy and surgery which he can there acquire might be more advantageously obtained, in the course of a few months, by the study of practical chemistry, by attendance at a druggist's shop, and by officiating as dresser in an hospital, or as a pupil at a dispensary. An apprenticeship may unhesitatingly be pronounced pernicious which absorbs either the means or the time that ought to be devoted to the acquisition of literary, scientific, or professional knowledge. And when we remember the circumstances under which a large proportion of medical apprenticeships are at present passed,—at a distance from any school, where either preparatory or professional knowledge can be acquired, and in the performance of a perpetual routine of menial services, which could be performed, with equal advantage to the public, by the most uneducated,—such apprenticeships cannot but be considered as an arrangement, in which the interests of those who are training to the medical profession are sacrificed to the interests of those who are already engaged in it. For it is in vain to expect, that even the most conscientious master can compensate to his apprentices, by his own instructions, for a want of those opportunities of

acquiring a knowledge of the different branches of medicine that are afforded by attendance on the instructions and lectures of professed teachers. And when it is considered how small a portion of provincial practitioners can have the time, even if they had the inclination and ability necessary for guiding the studies of their apprentices, we cannot be surprised that apprenticeships of this kind should be, as they are now very generally regarded by the liberal and enlightened part of the profession, more frequently the nurseries of idleness and ignorance, than of industry and knowledge."

From a conviction of the liability of apprenticeships to abuse, the College have, for some time past, abolished certain regulations formerly in force, which imposed a shorter and less extensive course of study on their apprentices than on other students; a change which must obviously be in some degree prejudicial to their own personal interest, by diminishing the temptation to young men to serve apprenticeships, and which, therefore, nothing but a sense of public duty could have led them to adopt.

The full courses of lectures on chemistry, and on materia medica and pharmacy, taken along with the course of practical chemistry enjoined by the regulations of the College, afford ample opportunities to the student for making himself acquainted with the principles of pharmacy, as well as with those of its more difficult operations which depend upon *chemical* combinations and decompositions. With the view of securing the more minute instruction of their licentiates in the *mechanical* parts of pharmacy, and in the compounding and dispensing of drugs, the College have it in view to make a regulation,—That, in future, all candidates for their diploma, who have not served an apprenticeship to a regularly licensed medical practitioner, who keeps a laboratory for the dispensing of medicines, shall be required to produce satisfactory evidence of their having attended, for at least six months, at the laboratory of a surgeon or apothecary, or of an established chemist and druggist, or of a public hospital or dispensary, and of having, during that time, been engaged in compounding and dispensing medicines.

In regard to the apprenticeship which, by the Apothecaries' Act, is rendered an indispensable qualification for examination before the Society of Apothecaries, it is particularly deserving of attention, that if the Society of Apothecaries be correct in supposing that, agreeably to the statute, this apprenticeship must be served to a person who has received a certificate of his qualification from the Court of Examiners of their own body, all medical students who receive their education in Scotland,

constituting the larger proportion of the medical practitioners educated in these kingdoms, are precluded from being taken on trial at Apothecaries' Hall.

To obviate the glaring injustice of this provision of the Apothecaries' Act, there was introduced into a bill to amend and explain it, which was passed in the session of 1825, a clause authorizing the Court of Examiners to examine apprentices to Surgeons. But as the duration of that bill was limited to a single year, and it has not since been renewed, the provision of the original Act respecting apprenticeships has again come into force.

[A comparison is then drawn between the courses of lectures prescribed by the College in Edinburgh and the Society of Apothecaries, for which, however, we are unable to make room.]

MEMORIAL OF THE SOCIETY OF APOTHECARIES.

To the Right Honourable LORD VISCOUNT MELBOURNE, his Majesty's Principal Secretary of State for the Home Department.

The Memorial of the Master, Wardens, and Society of Apothecaries of the City of London,

SHEWETH,

THAT the act for regulating the practice of apothecaries in England and Wales was passed in the year 1815, with the full concurrence of the medical profession in England, and was loudly called for by the then state of medical knowledge.

That the act has been impartially and honestly administered, and the Court of Examiners of the Society, by their attention to the medical education of students, and by requiring from time to time a progressively increasing course of study, now equal to the medical education required by any College in Great Britain, have most essentially improved the schools of medicine in England, as well as the state of medical science in general; and the general practitioners of medicine throughout England and Wales, who have been educated in conformity with the regulations of the Court of Examiners, are now fully competent to all the duties of their profession, and are entitled to, and actually possess, the confidence of the public.

That the power of examining persons who are about to commence practice as apothecaries can in no wise be considered a "monopoly," inasmuch as the persons

who examine the candidates for certificates of qualification have not the most remote interest in, or connexion with, any school of medicine, nor can any teacher in any branch of medical science become a member of the Court of Examiners.

That the clause in the act of parliament, whereby an apprenticeship of five years is required to be served by persons before they can be examined, was not proposed by the Society of Apothecaries, but was introduced into the act in the House of Lords. But the Society beg to remark, that a preliminary education, in the nature of an apprenticeship, is absolutely necessary, as well to lay the foundation for future acquirements as for the moral control of students from the age of sixteen to twenty-one, which control cannot be effectually exercised at any medical school or hospital.

That those persons who state that an apprenticeship is highly injurious to medical education, must be very ill informed upon that subject; for it is very well known that an apprentice has the opportunity of acquiring most valuable professional information from a suitable course of reading, under the direction of his master, and from seeing cases which occur in his practice.

That attendance on the physician's practice at an hospital does not afford to a student the whole of the instruction in practical medicine of which he stands in need, inasmuch as one-half of the deaths which annually take place are of children under five years of age, and of the aged above seventy, which cases are very rarely received within the wards of an hospital, but are attended almost exclusively by general practitioners, consequently coming under the observation of their apprentices.

That the different colleges and corporate bodies in Scotland who are seeking to obtain an alteration in the act of parliament for regulating the practice of apothecaries in England and Wales, by rendering the diploma of those bodies equivalent to the certificate of the Court of Examiners of the Society, are endeavouring to obtain for their licentiates a more extensive privilege in England than their diploma confers in Scotland; inasmuch as the diplomas of the university and of the Royal College of Surgeons in Edinburgh do not confer any right on the holders of them to practise as general practitioners in Glasgow, or within the counties of Lanark, Renfrew, Ayr, and Dumbarton, over which the jurisdiction of the faculty of physicians and surgeons of Glasgow extends; nor does the diploma of the faculty of physicians and surgeons of Glasgow confer any right within the jurisdiction of the College of Surgeons of

Edinburgh; nor can a person having a diploma or certificate from any college in England, or from the Society of Apothecaries, practise in Scotland without undergoing the examination, and obtaining the diploma, of the Scotch Colleges.

That numerous instances have occurred (several within the last twelve months) of graduates and members of Scotch universities and colleges having been rejected by the Court of Examiners of the Society, in consequence of their having been found incompetent to practise as apothecaries.

That should the prayer of the petitions presented to parliament by the Scotch universities and colleges be granted, one effect thereof would be to authorize those persons to practise immediately, who have on examination been found incompetent to do so without further professional study.

That the establishment of several different tribunals would give rise to very mischievous inequality of examination, and tend progressively to great laxity therein, and to lower the standard of the required attainments; more especially wherever it may happen, as it now does, at the different universities in Scotland, that the teachers are also public examiners.

That the admission of persons to practise as apothecaries who have not received certificates from the Court of Examiners of the Society, and been announced in the list annually published in conformity with the act, will deprive the public and the Society of the means of ascertaining the illegal practitioner, and will thereby give an opportunity for ignorant and incompetent individuals, to whom the health of the public cannot be safely entrusted, to commence and continue in practice in defiance of the act of parliament.

That the sums of money received by the Society of Apothecaries for certificates of qualification are not more than sufficient to defray the necessary expenses of enforcing the law against incompetent and unqualified practitioners, and the other necessary expenses of administering the act, and that no part whatever of the sums so received has been or is appropriated to the private purposes of the Society.

That there are now in England numerous schools of medicine, all of which, with the exception of a few in London, have been established since the passing of the act of parliament, at great expense to the parties who have established them.

That one effect in the alteration of the law sought for by the Scotch universities and colleges will necessarily be to prove a serious injury to all the schools of medicine in England.

That at these schools, including those in London, there are now attending nearly

1200 students, exclusive of nearly 2000 apprentices in other parts of the kingdom.

That 6498 persons have been examined by the Court of Examiners of the Society since the passing of the act in 1815, to 5769 of whom certificates have been granted, and the number of general practitioners in England and Wales is now upwards of 10,000 persons.

Your memorialists therefore beg to draw your Lordship's serious attention to these circumstances, trusting that due consideration will be given to a subject of such high importance to the interests of the profession and the public, and that an opportunity will be afforded to the Society to show, as they are prepared to do, that the act of parliament has been properly and efficiently administered, and to refute any statement which has or may be made against the Society, and to show that all the benefits which the act of parliament was intended to afford to the public have been fully attained.

By order,
(Signed) EDMUND BACOT,
Clerk of the Society.

8th May, 1833.

MIDDLESEX HOSPITAL.

CASES, WITH REMARKS, BY MR. ARNOTT.

Poisoning with Nitric Acid—Laryngitis—Laryngotomy—Appearances on Dissection.

I was summoned on Monday last at midnight, by our intelligent apothecary, Mr. Corie, to a patient who, having accidentally taken nitric acid that forenoon, had been admitted into the physicians' ward, and in whom, in addition to his other sufferings, violent laryngitis had supervened.

I found James K., a lad of 13, lying in a state of apparent stupor; his face pale; the skin cool, almost cold; pulse frequent, feeble, and intermittent every fourth or fifth beat; his respiration was rough and difficult, the quantity of air taken into the lungs appearing to the ear applied to the chest to be but small. On being questioned, he raised his eye-lids, and spoke in a whisper. His replies were brief, quickly delivered, and apparently attended with increased suffering; for to other interrogations he answered by a look or slight nod. From the reason just mentioned, he could not readily open his mouth when requested to protrude his tongue, which he did not do. He was unable to swallow even a tea-spoonful of fluid. He had great pain all about the

throat, from the front of which leech-bites were bleeding. On lateral compressure of the larynx, additional pain was felt. He had not vomited for some hours. There was no tenderness of the abdomen; and pressure on the region of the stomach gave no pain. As I sat by the bed-side the breathing became more laboured, and each inspiration was attended with a distinct low whistle.

I was informed that this lad, employed at a brass-worker's, had, about eleven o'clock A.M., laid hold of a bottle of aqua fortis, mistaking it for one of beer which stood near, and considerably resembled it, and drank out of it. The quantity swallowed could not be ascertained, probably a dessert-spoonful. He had vomited afterwards, and was vomiting when brought to the hospital, about half-past eleven. The tongue was swollen, and of a citron appearance; the uvula and tonsils were enlarged, as if œdematous; there was great pain around the larynx and pharynx, but none elsewhere. The pulse was small and feeble. The constant vomiting was promoted by frequent draughts of calcined magnesia. Towards two o'clock the sickness ceased, and he began to dose. At four the sleep partook more of slight coma; he was unable to swallow any fluids which got into the bag of the pharynx, and were directly returned. Respiration was rather hoarse, and the voice feeble. A mixture of gum, honey, and solution of chloride of lime, was employed to moisten his mouth. At six the coma had increased, though he was easily roused; the face was pale; pulse 120; but the surface, especially of the extremities, was cold, which prevented local depletion. At ten the skin had got warm, and of its natural temperature, but in other respects he was worse; the face was blanched; the pulse fluttering; the respiration more croupy and hoarse; and the lungs, which, up to this time, had been filled with air, now seemed to be so but very partially. Had had two motions of natural appearance. Fifteen leeches were applied to the throat.

That the boy, when I saw him, was dying, and probably would not survive above an hour or two, appeared but too evident; and the question which immediately presented itself was, in how far is the obstructed state of respiration contributing to the rapid progress of the case? That it *was* doing so I could not doubt; nor that, if left unrelied, the more immediate cause of the patient's death would be suffocation. But would an opening in the air passage, below the seat of obstruction, save the patient's life? The prospect was unfavourable.

The system had received a severe shock from the direct operation of the acid upon the parts to which it had been applied, and under this impression it still laboured. But could the system rally under the aggravation of obstructed breathing? This was not to be expected; and until it took place, the inflammation of the larynx, upon which the obstruction depended, could not be combated with success, or even safety, supposing the urgency of the symptoms had permitted the attempt. It was a vital object to gain time; laryngotomy, by prolonging life, would afford nature an opportunity of recovering her powers; and as it offered a chance, and the only chance, attended too with little or no additional risk, I determined that the patient should have it. The same operation had saved life in a case where the mouth and throat had been scalded by boiling water drank from the spout of a tea-kettle; and although the destructive agent in the present instance was infinitely more severe, yet the analogy in circumstances was sufficiently close to justify some hope that it might here also be attended with benefit.

The larynx was opened in the usual place. In reaching it a vein was divided, which spouted, and would have bled freely, but a finger being placed on it, the division of parts was continued until the crico-thyroid ligament was exposed, and as much of it bared as it would be requisite to excise. The vein had now ceased to bleed, but two arteries required ligatures; and the general oozing was so free as to render it necessary to wait about ten minutes until it had ceased, when a piece of the crico-thyroid ligament was removed. Immediately on its being penetrated the air rushed out, a little frothy secretion was expelled, and for some time the edges of the divided mucous membrane, which was observed to be of a dark red, or rather purple colour, gave out blood in a way which required that this should be absorbed by the repeated rapid application and withdrawal of a sponge. The sides of the wound in the parts external to the larynx were kept asunder by a bent loop of wire applied to each side.

The relief to respiration was immediate; the muscles of the neck and chest ceased to act, those of the abdomen alone shewing action, and the patient fell into a calm sleep. In an hour after the operation the pulse was less frequent, more regular, and of greater size.

At ten A.M. on Tuesday there was less of the apparent stupor, and more liveliness in the eye; respiration free, but frequent, and carried on entirely through the wound. No cough; pulse 120. Calomel grs. iij. 2dis horis.

One p.m.—The calomel has passed in part, if not wholly, through the wound in the larynx. Cannot swallow better. No increased secretion of mucus from bronchi or trachea; respiration more frequent. Injections of beef-tea per anum. In the evening he became restless, the temperature of the skin sank, and he died at half-past ten, twenty-two hours after the operation, thirty-six after the accident.

Examination of the Body sixteen hours after death.—No discolouration or abrasion of the integument of the chin or lips. Teeth of usual white appearance. Upper surface of the tongue of a grey and citron colour, the former predominating at the tip and sides, the latter in the middle. The alteration in colour was seated in the cuticular covering of the part, which was separating, and hanging loose for some extent all round the edge of the tongue, and fairly detached from a part of its base, leaving the surface red, the papillæ bare, enlarged, and prominent. Membranous shreds hanging from both tonsils. The pharynx and upper third of the œsophagus were covered by a continuous, grey-coloured, slightly lemon-tinted, membrane, which was corrugated and dry, and thrown into longitudinal plicæ, marked also by transverse lines. This membrane, the epithelium of the part, had become completely detached from the two lower thirds of the œsophagus, in which large portions of it remained loose, two or three small spots excepted, which were still covered with it; one of these close to the termination of the tube at the cardia. The surface from whence the epithelium had separated presented almost its natural smoothness, but was a little rosy in colour. On raising the lower edge of the portion of epithelium attached to the upper part of the œsophagus, the subjacent surface was red, which in some points had an arborescent character. The chorion of the œsophagus, especially of the upper part, was thicker than natural. The stomach internally, generally red, contained some yellowish brown, pappy, glairy matters. Its inner surface exhibited no softening or abrasion, or any unusual appearance, with the exception of one place, the size of a crown-piece, on the lesser curvature, on which were scattered a number of ochre coloured spots, the size of a pin's head, the colour in question being seated in the mucous follicles of the part, or gastric glands. The commencement of the duodenum had a healthy appearance.

The edges of the entrance of the glottis were extremely tumid; the surface at the same time corrugated; the colour lemon; but at two places, on oppo-

site sides, of an orange colour. The epiglottis, of a brownish colour, was not merely corrugated, but shrunk in size, so that it could not be brought over the entrance of the glottis. The internal surface of the larynx, through its whole extent, from the opening of the glottis downwards, and the adjoining upper third of the trachea, was covered by a very thin delicate layer of lymph, which could be raised from the subjacent surface of the mucous membrane, which was here pale. Lower down, the mucous membrane of the trachea was of a deep red colour, and with no appearance of lymph. The bronchi also were red, but contained no diseased mucous secretion. The posterior parts of the lungs were loaded with blood.

As instances of poisoning by nitric acid are not very frequent in this country, there are some circumstances connected with the above case, as regards its history, treatment, and the morbid appearances, to which I may be permitted now briefly to advert. And first, with respect to the state of the stomach when the acid was taken, and its quantity. By inquiring of the friends with whom the boy lived, I learnt that he had breakfasted in his usual hearty manner at nine o'clock upon bread and butter, and milk and water. From the master with whom he worked I learnt that the accident occurred a few minutes before eleven; that the lad could not have swallowed much, for "he spat out a table spoonful, but must have swallowed some to enable him to draw breath: he had one gulp." Water was given him to drink immediately, and he was then taken to a neighbouring chemists. There, at 11 o'clock, a solution of carbonate of soda was administered; which had hardly reached the stomach when vomiting took place, with great effervescence, and the ejection of a quantity of brownish looking stuff, sufficient to fill a small basin, frothing like yeast. The vomiting, it has been stated, continued when he was brought to the hospital, and was encouraged by draughts of calcined magnesia.

From the state of the œsophagus, ascertained after death, and more especially of the lower part of it, it is almost certain that some of the acid got into the stomach, and the reason of this viscus having escaped serious injury is referrible to its having been still filled with the food which had been taken at breakfast. Was the ochre-like colour of the gastric glands near the pylorus dependent on the acid having come in contact with them? It is probable, and yet the mucous coat around them was not injured.

With respect to the symptoms in this

case, they corresponded with those described by the best authorities as being produced by nitric acid, both in regard to the local appearances and the constitutional effects. Among the former the *citron* colour of the tongue was particularly marked; and of the latter, "*the feeling of cold*," which is stated by Orfila to be "*un phénomène commun à beaucoup d'empoisonnements, mais très marqué dans l'espèce (l'acidité nitrique) dont il s'agit ici—il persiste fort long tems*,"—was equally so. When the boy was taken into the ward he was so cold that the nurse was obliged to put him in warm blankets, and the history shews that this continued. The pale face, and the state to which I have applied the term *apparent stupor*, was singular. I have said apparent because there was no real stupor; the lad's intellects were perfect; his attention was alive at once to a question when put, and which he replied to without any of that peevishness which accompanies stupor from concussion of the brain. This state of apparent stupor preceded the affection of the respiration, and therefore was not dependant or connected with any interruption to this function: it set in immediately after the vomiting ceased, which probably, while it lasted, prevented its being noticed. The state to which I am now alluding corresponded, in fact, to that prostration or collapse which so often immediately succeeds severe injuries—amongst others, burns: to it his death must be referred. There was no affection of the stomach to occasion this; the obstruction to respiration was obviated by the aperture made in the air-passages below the seat of it, and these passages remained free to the last; but the system never recovered from the shock it sustained by the violent injury done to the œsophagus, pharynx, and mouth. The continuance of this state of prostration prevented the adoption of those measures of depletion which were provisionally ordered after the operation as requisite for the cure of the laryngitis and pharyngitis.

The propriety of the operation of laryngotomy in this case will not, I think, be questioned: it certainly prolonged the patient's life; and under more favourable circumstances, viz. less severe injury, might have been the means of allowing life to be preserved. In deciding upon its adoption I was influenced by the recollection of Dr. Hall's and Dr. Burgess's papers on the performance of laryngotomy in cases of laryngitis from scalding of the mouth and throat by drinking hot water from the pipe of a tea-kettle.

I am not aware that this operation has been previously performed under similar

circumstances of poisoning by acids; but the occurrence of inflammation of the larynx, in cases of death from the administration of strong acids, has been repeatedly noted. Dr. Christison remarks, that "a great number of the irritant poisons (of which the strong acids are the first) cause hoarseness, wheezing respiration, and other signs which indicate the spreading of the inflammation of the throat and windpipe." And at another place, referring to the manner in which they may prove fatal, he even remarks, "It also appears exceedingly probable, although no systematic writer has, to my knowledge, laid it down, that the strong acids may cause death, without reaching the stomach or even the gullet, by exciting inflammation and spasm of the glottis and larynx."

I have said above that the propriety of the operation of laryngotomy, in this case, will not, I think, be questioned. Perhaps I ought to have put it differently, and said tracheotomy; as some may be disposed to prefer this operation. I selected laryngotomy in the present case, because by it an opening was made in the air-passages equally below the seat of obstruction, and because it is a more certain and a more safe operation. Two instances have occurred in which the trachea has been attempted to be opened in children, but without success; and there are other cases where the hæmorrhage has been so free as to cause the operation to be abandoned, or deferred, or which have rendered it extremely difficult of execution, and caused it to be attended with great danger afterwards. I do not think that the possibility of the inflammation having descended to that part of the larynx in which the aperture is made, is a countervailing disadvantage. Even supposing this had occurred, it would in no way interfere with the great object of the operation—the free admission of air to the lungs; which would still be obtained.

It has been represented by Orfila, following, I presume, Tartra, that in cases of poisoning by nitric acid there is found on the surface of the œsophagus, "*un enduit de matière jaune, grasse au toucher, qui paraît formée à la fois par de l'albumine coagulée et par la membrane muqueuse altérée d'une manière particulière*." And Dr. Christison, in describing the morbid appearances caused by the mineral acids, states, that "the gullet is often lined with a dense yellow membrane, adhering firmly, resembling the inner coat, but probably a morbid formation." As regards the fact of the œsophagus being lined by a membrane, these writers are correct; but the representation that this is

formed of "concrete albumen," or that it is a "morbid formation," by which I understand that it is a product of inflammation, is certainly erroneous.

In the present case it was clearly the epithelium, or cuticular covering of the œsophagus, simply and alone, changed by the direct action of the acid; at the upper part of the œsophagus still adherent to the subjacent chorion, at the lower separated. On comparing it with the epithelium of an œsophagus which had been subjected to maceration for three or four days, and when this epithelium could be removed as a membrane, the fact was confirmed, if confirmation had been wanting; but there was this difference between the two—that in the one the membrane was soft, white, and translucent; in the other it was hard, of a greyish-lemon tint, opaque, corrugated, and dry.

The contrast, too, between the appearance of the pharynx and œsophagus lined with the epithelium, changed as just described, and the larynx lined with a thin very delicate layer of lymph, was striking, and particularly at the entrance of the glottis, where the two came almost into continuity, and were separated only by a line's breadth; the one being the effect of the direct application of the acid to the part, the other being the result of inflammation excited in it.

While upon the subject of laryngotomy, in connexion with disease of the larynx, I am induced to advert to another case which recently occurred in the hospital. In the one which has been related, the pathology of the disease (laryngitis) requiring the operation, is known, and its treatment established; but in that about to be detailed, neither the one or the other is the case. In the former, inflammation of the living membrane of the larynx is to be combated by remedies which experience has proved to be successful; in the other, diseased changes were going on in textures beneath the mucous membrane; and even if the condition of the parts, as found after death, had been known, the appropriate treatment is not easily ascertained.

Sore Throat—Dysphagia—Loss of Voice—Obstructed Breathing—Laryngotomy—Appearances after Death.

On the 21st of March I was requested (in the absence of one of my colleagues) to see J. S., to decide on the propriety of making an aperture into the larynx, and to perform the operation, if necessary.

This patient, a man between 40 and 50, had been admitted three weeks previously, with fistula perinei and stricture of the

urethra. Ten days ago he was attacked with sore throat, and for the last eight he had not been able to swallow any thing but fluids, and that with great difficulty. He lost his voice on the evening of the day on which he first experienced difficulty of swallowing. Two days ago, his countenance was anxious, the breathing hurried, accompanied by a gurgling, but not crouching; air was heard to pass through the larynx, with a sibilous noise occasionally, and freely into every part of the lungs. Pain was referred to the pharynx, and chiefly to the left side of it. None on pressing together the alæ of the thyroid cartilage. Yesterday (the 20th) he expressed himself relieved by the leeches applied, but respiration did not seem to be improved, although he stated that it was so. During the night his breathing became worse, and the apothecary was called to him early in the morning, when twenty leeches were applied. With the exception of delirium, I found him at 10 o'clock suffering and apparently sinking under the symptoms above described. The breathing laborious, attended with a rattling in the throat, the countenance slightly livid, but not anxious. The stethoscope to the chest discovered nothing, the noise in breathing preventing it. A blister having been applied, three days previously, over the front of the neck, (the surface of which was still sore,) rendered manual examination of the pharynx and larynx fruitless. Nothing amiss could be discovered in the posterior fauces by inspection.

The history of the case, the state of the patient, and labouring action of the larynx, shewed that there was some obstruction to respiration seated here; but the impression produced was, that this was not sufficient to account for all the distress existing. The bronchial mucous membrane appeared to be inflamed. Was the patient's condition beyond recovery? Would it be of any avail making an aperture in the larynx? The disease had begun in the pharynx and extended to the larynx. Under similar circumstances I should take the chance which laryngotomy afforded: the slight nature of this chance was communicated to the man's wife; it was mentioned to himself, and he caught at it (as I have ever seen patients with obstructed breathing, from laryngeal disease, do). In the inter-muscular cellular substance lymph was found effused at one place. The cricothyroid ligament being divided, a table-spoonful or two of reddish-coloured mucus was immediately thrown out of the opening by coughing. The breathing was relieved of the more urgent distress, and the man fell a sleep for about an hour.

He afterwards continued to breathe entirely through the wound, but respiration became more frequent, he continued to sink, and died nine hours after the operation.

On examination of the body, coagulable lymph and pus were found effused at different parts into the cellular substance, all along the front of the larynx and trachea to the bottom of the neck, and some lymph into that of the anterior mediastinum. The pus and lymph were in greatest quantity on the left side of the upper part of the trachea.

In the pharynx, the entrance of the glottis was the seat of three ulcers, which occupied both edges of this aperture, without involving the mucous membrane of the larynx. These ulcers, however, burrowed deeply under this membrane, so that the probe could be passed in some directions, more especially forwards towards the angle of the thyroid cartilage to the extent of an inch. In the interjacent cellular substance of the larynx and pharynx, and amongst the muscles of the glottis, were in several places small abscesses; and on the left side, between the mucous membrane of the larynx and the thyroid cartilage, was one containing a tea-spoonful of thick yellow matter.

The superior chordæ vocales might be a little thickened, but the mucous membrane of the larynx presented no other evidence of disease. There was some redness of the upper part of the trachea, increasing in intensity lower down. The bronchi were still more red, and their surface was covered with threads of puriform mucus. The lungs were loaded with blood. There was effusion into both sides of the chest of red coloured serum. The pleuræ were no way adherent.

The primary affection in this case was no doubt that of the throat; but did ulceration take place first, or were the ulcers the consequence of abscesses of the part breaking? It could not be ascertained from the friends that this man had been the subject of secondary syphilis. The effusion into the pleuræ, and the reddened, perhaps inflamed, bronchial membrane, were the result of laborious respiration from obstructed glottis. If the operation of laryngotomy had been performed sooner, both these consequences might possibly have been prevented; but how ought the burrowing ulcers of the pharynx and larynx, and the abscesses in the cellular substance of the latter, the chief cause of obstruction to the passage of air through the larynx, even if discovered, to have been treated?

Prevailing Wind, S.W.

The afternoon of the 9th, cloudy, with a light shower about three; otherwise clear.

CHARLES HENRY ADAMS.

NOTICES.

"C. L." The Letter has arrived quite too late, we fear, to be of any use; although written "on the eve of the assembling of a reformed parliament."

We do not understand what a correspondent means by signing himself "An Article Student of the College of Surgeons!" The subject of his note, however, shall not escape our attention.

The Letters of "F." have been deferred for want of room.

We have received several Letters relative to the Society of Apothecaries, some of which we shall give next week.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

DISEASES OF THE CHEST.

PHTHISIS PULMONALIS.

HAVING gone over the chief points of the morbid anatomy of phthisis, I shall now proceed to consider the

General Symptoms.—This is for the most part a very slow and insidious affection. Long before any other symptom occurs, it is very common for the individual to be seized with hæmoptysis—spitting of blood. This, as I mentioned when speaking of hæmoptysis, or hæmoptoe, as it is called, is usually from the bronchial membrane. The blood is of course frothy, scarlet, mixed with air, and occasionally it is in considerable quantities, but for the most part it is not to any great amount. The patient frequently has several returns of this, before any other particular symptom of phthisis presents itself. When phthisis occurs, then, for the most part, there is little or no more spitting of blood. Whether this has occurred previously or not, one of the first symptoms noticed is a short tickling cough, such a cough as the patient denies even to exist. It is observed by his friends, while he himself for the most part complains little of it, or, if questioned on the subject, denies it altogether. The cough is short, tickling, and hacking, rather than very severe. With this cough there is for the most part spit up only a little mucus, either at the same time, or soon after its commencement. It is very

common to hear the patient complain of a stitch in the side, generally low down, either on one side or the other; and one would think it was a little pleuritic affection, only that sometimes it is undeniably felt beyond the chest, in the parietes of the abdomen. I have known a very violent stitch, before any other symptoms of phthisis, low down in the abdominal muscles, out of the way of the chest; so that these pains, though they are occasionally pleuritic, are, I have no doubt, very frequently muscular. The cough is generally worse when the patient gets into bed, from the coldness, I presume, of the sheets; or, when he rises in the morning, from the coldness of the atmosphere of the room compared with the warmth of the bed. There is felt a little shortness of breath on motion; on any exertion, the patient finds that his breath is not so good as before, and he complains of languor. The flesh becomes soft, so that on taking hold of the arm of a patient, even at this time, you find it is flabby. The hair loses its strength, so that it cannot be kept in order as before. You observe this particularly in females. There appears to be a softness of the hair, which will not allow it to remain in the way in which it has been placed. There is observed too about this time a little feverishness; the pulse is found to be quicker than natural, and this has particularly come on on the least exertion. An exertion which before would quicken the pulse only perhaps ten beats, will now quicken it twenty or thirty, in a minute. On falling asleep, it is very common for patients to find that they sweat in some one part of the body—in the calves of the legs, or upon the chest. The power of resisting external temperature is diminished, so that he complains of chilliness. The expectoration, although only mucus originally, is now streaked with a little blood. Perhaps the patient never had hæmoptysis, but the complaint has begun with the

general symptoms I have mentioned, and the expectoration was mucoous; but he tells you on one of your visits that what he has spit up was brown, or tinged with blood. That is another form, in which a discharge of blood takes place. Very frequently there is the hæmorrhage which I before mentioned, but perhaps more frequently there is no such thing as any decided hæmoptysis, but the mucus after a time becomes a little streaked with blood.

There is now more cough, more dyspnœa and more debility than before, and the patient begins to find that he lies more easily on one side than on the other. The patient finds his strength decrease; or if he do not himself allow it, yet it is evident to others. He cannot make the same exertion as before, and it is also pretty evident that he loses flesh. Occasionally there is a sharp pain in the side, of a pleuritic character, so as to make it necessary to take away a little blood; there is clearly inflammation of the pleura. If the patient be a female, menstruation is almost sure to decline; the catamenial discharge loses its natural redness, becomes paler than it should be, and more scanty in its quantity, as well as being thus impaired in its quality; and more frequently than not it ceases altogether. You will generally observe that, as these symptoms all proceed, the ends of the fingers become enlarged; the last joints of the fingers look broader than they did before; you will find that the whole appear tumid, and that the nail is particularly prominent. The eyes too become very clear; you observe a whiteness and transparency of them which you did not see before; the sclerotica looks of a more intense white than natural. The nails sometimes become incurvated—bent very considerably; the whole nail is more convex than before, and I believe rather softer, like the hair; and that part of the nail which is unattached to the cutis, is in many instances very much bent. The weakness of the hair now is such, that whether the patient be male or female it falls off. The hair, which at first is only soft, and with difficulty is kept in order, now generally becomes scanty. The expectoration, from being more frothy mucus, now becomes a little green, or a little yellow, and more abundant; and instead of being long and stringy, like the expectoration of health, it becomes short between the fingers. Now and then the expectoration becomes fetid, the strength very much declines, the sweating at night becomes very profuse, and the expectoration decidedly sinks in water, whereas before, either the whole of it, or the greater part, swam. Shreds are seen in it whiter than the rest, like curdy lumps, or fragments; and in some few instances you

observe earthy matter in it. The latter is by no means so frequent an occurrence as the former, but you see it now and then. The tongue will sometimes remain in a healthy condition, but in most instances it becomes loaded with mucus, and is foul and yellow, on the one hand, or it becomes red at the edges and tip, on the other. Sometimes it is of an intense redness all over, so that it looks like a piece of beef.

There is now an increase in the pulse at least twice a day—that is, in the middle of the day and in the evening, but decidedly in the evening; there is a great exacerbation of it, together with heat of the body after every meal. The urine deposits a pink sediment; the pink sediment of hectic appears, and the pulse is constantly much quicker than it should be, perhaps seldom below 90, and frequently above 100. The mind and the appetite remain unimpaired. Persons labouring under this disease will frequently eat heartily to the very last, have a perfectly good digestion, and their mind is as alive and active as it ever was—perhaps more so. Patients generally have hope; they will not believe that they are in a dangerous state; they do not think that their case is consumption. On the other hand, when people are not active, and think they are labouring under phthisis, in nine cases out of ten there is no danger whatever. A remarkable feature in this disease is extreme hope, so that medical men who have fallen victims to phthisis have insisted up to the day of their death that they have not had ulceration of the lungs, and that they should get well. This has been observed in intelligent men, as well as in those who were most stupid. It is not a matter of judgment, but of feeling; and hope in this disease is exceedingly remarkable, quite characteristic of it, though it is by no means an invariable circumstance. Now and then you will see persons despond; they are quite aware of their situation in this disease when it is well established and confirmed, but in a much greater number of instances there is the most lively hope; patients will not believe that there is any danger.

Colligative Purging and Sweating.—In the greater number of cases the intestines suffer very much. Perhaps at the beginning the intestines are a little dormant, but as the disease proceeds, and especially at the last, the intestines fall into a state of diarrhœa, and the purging very frequently alternates with the sweating. The purging is so severe, that you may say it melts down the patient, and it is called *colligative purging*; and the sweating is so profuse that it is called *colligative sweating*. The expectoration of course becomes more yellow and green than before, and it also

becomes more abundant; the cough becomes more severe; the legs become œdematous; and the body wastes exceedingly. The hectic flush is seen decidedly upon the cheeks and palms of the hands; and the exhaustion is such in some cases, that the patient frequently faints; he feels of course exceedingly languid. The patient is at last confined to his bed in all cases; but in some instances there is great tendency to syncope, and dyspnœa from debility—so that stimulants are required; and just before death the brain is sometimes affected, so that there is delirium frequently three or four days before death.

Varieties in the progress of the Symptoms.—The progress of all these symptoms is exceedingly various; sometimes only a few weeks, but in other cases many years, elapse before the patient sinks under the affection. I am convinced that I have seen cases where there were no symptoms of phthisis, and yet the patient has died from ulceration of the lungs in the course of three months. I recollect one instance of this particularly. On account of some anomalous symptoms in the abdomen, the patient was continually examined by me. He was two or three miles from London; and on carefully examining his chest, I found that he was free from cough, free from all the symptoms of phthisis generally, and from those symptoms which can only be learned from auscultation. He then began to spit something, shewed signs of phthisis, and died. On the autopsy we found ulceration. All this occurred in the course of two months. The public at large are aware of this state, and they give to such cases as these the epithet *galloping consumption*. On the other hand the disease will last, there can be no doubt, very many years—that is to say, persons will have cough, and spit matter; yet it will not increase, but decline from time to time, and so they will go on till at last they expectorate a great deal, and die in the usual way. Dr. Gregory, of Edinburgh, used to say that he knew a case where a person was in a state of consumption for fifty years; but it is impossible to say that the patient laboured under phthisis all the time; it might have been only bronchitis. But it is a fact, that there is a very great variety as to the duration of the disease. It is generally quickest in those who have the finest skins, and are nearest the period of puberty, or who are not very much beyond that period. The disease is frequently suspended, on the other hand, by pregnancy, and by suckling; and now and then it has been suspended by other diseases—by ague or insanity. These, however, are only occasional circumstances.

You will now be prepared to understand the symptoms that take place during the progress of this disease, acquirable by the ear.

Auscultatory Signs.—At the first period of phthisis there is nothing at all to be learned from the ear; at least I believe not: it is from the general appearance of the patient, and from the general symptoms of which he complains, that you suspect that phthisis is present. At the onset, it is at most only a matter of suspicion: you cannot be certain of it. You will easily see that this must be the case, when you consider that, in the first instance, the tubercles which constitute this disease are exceedingly small and exceedingly few, leaving a large portion of pulmonary structure perfectly healthy. It is only when the tubercles increase to a certain size, and approximate, so as to form a mass, that you can expect any symptoms that are discernible by the ear; it is only when a considerable portion of the pulmonary structure is beset with tubercular deposit, that you can expect to discover any audible change. The parts in which the symptoms acquirable by the ear are to be noticed, in the first instance, are below the clavicles. This may be observed before the tubercles have softened; but when they become sufficiently large and sufficiently numerous to occupy some space, on striking over the part where such deposit exists you will not find the hollow sound of health, but a greater degree of dulness than there was before. In proportion to the size of the tubercular deposit is the dulness of the sound; and you may save yourself a great deal of trouble by beginning your examination at the clavicle, and immediately under it. Still, if you have any suspicion, and yet you find the parts below the clavicle sound well, you should examine other parts; because now and then the deposition, instead of taking place there, occurs in other situations. In the great majority of cases, however—I may say nine cases out of ten—the change takes place just below the superior portion of the lungs, and therefore you should commence your examinations there. Besides this dull sound on percussion, if you listen with the stethoscope, and make the patient speak, you will find the voice resounds there in an unnatural manner. The solid substance of the tubercles is so much better a medium of conveying sound than the loose structure of the healthy lung, that the sound is louder where these tubercles exist than elsewhere. The voice will not come through the tube, as if the patient's mouth were at the other end of it, speaking to you, but you hear the sound echo, and you hear it louder than natural. You have no pectoriloquy, but you have

what is called *bronchophony*—the same sound that you hear in putting the stethoscope over the large bronchiæ. But it is to be remembered, that the voice sounds louder under the clavicle naturally than elsewhere, on account of the large tubes being there; and consequently you should not depend on this symptom alone. It should be united with the dead sound on percussion, to make you satisfied that there is bronchophony dependent upon tubercular deposition. It is well to compare the sound on each side; for the deposition generally takes place more on one side than on the other, and frequently it occurs only on one side; and your suspicion will be increased, as to the really unnatural loudness of the voice, if you hear it louder on one side than on the other. You will be much more satisfied of the real existence of this disease, by comparing the sound of both sides, than if you merely attend to one: the difference of the two is frequently very manifest.

Pectoriloquy.—But when the tubercular mass softens, and a portion is discharged, so that the cavity is emptied, or nearly so, you have a new symptom. The bronchial tubes, you know, enter this cavity; and as the air enters it, you have the same state of parts there that there is in the trachea—that is to say, there is a large space, into which, on inspiration, the air enters; and consequently, when the patient speaks, you will have the same sound that occurs on putting the stethoscope over the trachea. If you place the stethoscope over the trachea, you have the voice traversing the tube, as though the mouth were at the other end; and just the same occurrence takes place when you put the stethoscope over a cavity in the lungs: you have the phenomenon called *pectoriloquy*. If you make the patient cough, you hear a mucous rattle—the same sound as if air were forced through soap-suds; a gurgling sound, arising from the air agitating a viscid fluid. But as the contents grow less and less viscid—as the curdy matter of the serofula is more and more spit up, and mere mucus forms more and more the contents of the cavity—the gurgling is heard louder, and is found to be freer. Then, if you make the patient breathe quick, and at the same time rather deep, you hear the same sound that you do if you make him breathe quick and put the stethoscope over the trachea. In the latter case, you have the sound of the air evidently going through a large space; and the same circumstance occurs in the former instance, merely arising from the part being the same as the trachea. You have the same phenomena with respect to simple respiration—the same phenomena

with respect to the voice when the patient speaks, and the same phenomena when you make him cough, that you have when you place the stethoscope over the trachea: that is to say, you have pectoriloquy. You may, however, if you listen over a certain part of the chest, have the same symptom of pectoriloquy in the most perfect health; especially in thin persons. If you place the stethoscope, in a person who is thin, between the clavicles, you have pectoriloquy, arising from the large bronchiæ going to the lungs emitting the sound of a tube, even if the individual be healthy. You must not, therefore, pronounce a person in a state of phthisis simply because you have pectoriloquy between the clavicles, but when you hear it in other parts of the chest decidedly, then there can be no doubt as to the nature of the case.

When things have come to this pass, you no longer have the dull sound on percussion that you had in the first instance. The tubercular solid mass which gave the dull sound on percussion no longer exists, and consequently there can no longer be the phenomenon which it produced. That phenomenon was a dull sound, from the part being solid; the part is now hollow, and on striking over it you find the sound as hollow as in health, and perhaps more hollow. It is to be remembered, that though you have pectoriloquy, and you thus have a large space which ought not to be there; yet the phenomenon does not shew the nature of the cavity, and it is only from the general symptoms that you are satisfied it is the cavity of phthisis. You will recollect that I mentioned, when speaking of gangrene of the lungs, that a part of the lung is sometimes separated, discharged, and a cavity will exist, from that circumstance; so that you may have pectoriloquy from gangrene of the lung. But then you know that it arises from gangrene by other circumstances—such as the great debility of the patient and the fetor of the expectoration. You may, from chronic bronchitis, have the bronchial tubes very much enlarged at one spot—as large as the bronchiæ themselves, or approaching to their size—and in that case you will have pectoriloquy; but then there will not be present the general symptoms of phthisis, and thus you will suspect the nature of the case. You see that no reliance is to be placed on the ear alone; that the symptoms which are audible are only to be taken in conjunction with those which are general; and persons find fault with auscultation unjustly, who suppose that it is employed to the exclusion of attending to other symptoms. No person who uses his ear is justified in making so absurd an use of it: the person who is

disposed to employ his ear ought to be careful in adopting all the means within his power of making observations. A person may be labouring under ulceration of the lungs, and yet he may not afford the sign of pectoriloquy. If the cavity be near the surface of the chest, and the walls of the cavity be very thin, and if the bronchial tubes that open into the cavity have mouths so small as to bear no proportion to the cavity itself, you may have a large cavity, and yet no pectoriloquy at all. Here, again, is an instance of the fallacy of the observations made by the ear alone, to the exclusion of the other symptoms. I have, over and over again (as every body has who has attended to these matters), opened patients, and found a large cavity after death, where, before the fatal termination of the case, there had been no pectoriloquy at the affected spot. The walls of the cavity must be a certain thickness for the phenomenon of pectoriloquy to be produced; and the bronchial tubes opening into the cavity must bear a certain proportion to it; but when the cavity is near the surface of the lung, and the substance of the lung has been entirely destroyed, so that there is merely pleura forming the parietes of the cavity, you will cease to have pectoriloquy. If, however, you had seen the patient before the cavity became so large as to be out of proportion to the bronchial tubes opening into it, and the walls became so much diminished, then you would have had pectoriloquy. But you may not have been called in before the patient arrived at this state, and therefore may not have had an opportunity of observing the successive changes.

Metallic Tinkling.—When an excavation is very large indeed, you will sometimes have another phenomenon—you will have what is called *metallic tinkling*. By this is meant a sort of silvery, ringing, metallic sound when the patient coughs, speaks, or breathes; but particularly when he coughs—a clear metallic ringing, which can hardly deceive you. But the sound is not peculiar to this affection; for when the surface of the lung is ulcerated, and air escapes into the pleura, that being a very large cavity, it just gives you the same phenomenon. When air enters into the pleura, from the presence of the air and fluid together you have metallic tinkling; but if it so happen that there be a large cavity in the lung, that will come to the same thing, and the air and fluid entering into it will give rise to the same sound. The cavity, however, is seldom so very large as to produce it.

You seldom examine a patient at that point when much information is to be derived from the ear. In the first stage of the disease there is nothing to be learned

from it, and as the disease proceeds the case is generally perfectly clear, without the use of the ear; but if a set of symptoms do present themselves to the ear, they are as worthy of being observed as those that present themselves to the eye; and the mere trouble of examining them can be no excuse for not observing them. Unfortunately, in the great number of instances, the case is too severe to render such examination necessary, but cases do occur where the disease is not so severe, and some will say that the affection is bronchitis, while others assert that it is phthisis. Persons are said every day, by those who do not use the ear, to be in a state of phthisis who are not, and *vice versâ*. Now if the ear be used after a certain time, and we ascertain the existence of a cavity (because, if you examine a patient late, the phenomenon of pectoriloquy may have ceased), this, in conjunction with the other symptoms, will render the case clear. It is of great importance to be able to say that there is pectoriloquy; for a practitioner may have said that it is not phthisis at all, and he will stick to it; but if you listen, and hear pectoriloquy, you may be sure that he is wrong, and may be able to convince him of it. It is a fact that some practitioners who have taken a predilection for other organs—particularly the liver, or the viscera of the abdomen—declare that there is no such thing as phthisis present, while it is evident enough that the patient's lungs are rotten. Now if, in a case like that, you can induce a person to condescend to listen to you, and can shew him the difference between the sounds in health and those in this disease, you may open his eyes, or you may bring forward such an argument as cannot be resisted. It would be unphilosophical not to know these things, and not to attend to them if they do exist.

Respecting the prognosis in this disease, when you find such a state of things as this, it must be always unfavourable. If only one part of a lung be beset by tubercular deposition, it is possible that the substance may soften, be expectorated, the part heal, and the patient do very well. It is possible that you may have pectoriloquy, that you may have signs of confirmed phthisis, and yet the patient *may* recover: such things, however, are exceedingly rare. I doubt whether it is a very common thing for these excavations to heal at all; but it is a far more uncommon thing for the patient to get well; because, in general, the disease is constitutional, and if one excavation should heal, a crop of tubercles occurs in some other part, which will go through successive changes, and under these the patient will sink. When you open a patient who has died of phthisis, you

almost always find tubercles in various stages, and if you could heal one lung entirely, as it has been proposed to do, by making an opening into the chest, and causing the lung to collapse, I doubt, then, whether you would do much good; because the other lung is generally beset with tubercles, which will regularly go through their stages in the same way. But I do doubt very much whether these cavities so frequently heal as has been supposed. I am quite sure, on account of the succession of tubercles, that persons rarely recover; and I doubt whether the cavities heal so often as Laennec thought they did.

Cicatrization a rare occurrence.—Laennec says, that he has frequently seen in the lungs a cicatrix; that a cavity had existed and healed; that the sides had come together, and the part become solidified and hard, just as is the case with the surface of the body. The appearance spoken of by Laennec as indicative of a healed cavity, is a depression on the surface of the lung, a puckering, just as in a cicatrix on the surface of the body when there has been an abscess below. If there be merely superficial ulceration you know that a scar is left; but in proportion to the depth of the ulceration on the surface of the body, and the parts immediately below the surface, so is the depth of the cicatrix and the puckering. This appearance is sometimes seen on the surface of the lung; and he says, that, on cutting down on such a part, you find induration below it of a greater or less depth. My reason for doubting this is, that you see exactly the same appearances upon the liver. Almost every month, if you open many bodies, you find a puckering on the surface of the liver—a depression, with a puckering all around it; and, on cutting into it, you find the substance of the liver unnatural as to colour, but there is no ulceration, in fact there could have been no ulceration, no suppuration, for there are no signs of there having been any matter. The peritoneal surface of the liver will fall into a state of chronic induration; here and there it will become indurated and hard, and it is commonly puckered; and there you have the appearance of so many scars. Now the same thing, I know, will take place in the lungs. You may see them puckered, and you may see the pleura very hard there, but I cannot see that that is any reason for believing that there is a cicatrix. And you may be deceived from finding a large track of some depth down the lungs, (which should not have deceived Laennec,) from a mere cohesion of the different lobes of the lung. It is common, when there has been a slow thickening of the pleura, to say nothing of inflammation, to find the

lobes glued together, and the pleura between the lobes thick and almost cartilaginous, and sometimes there is a puckering on the surface; and, on cutting down, you find a cartilaginous hardness to some depth, but on careful examination you find the cohesion of the different lobes. Independent of that, the pleura will fall into the same sort of disease as the peritoneum all over the liver, and produce just the same appearances. On reading Andral, I find that he has come to the same conclusions as myself, and I have no doubt that others have done so likewise. It is said that now and then a cicatrix may be produced, but I am sure it is a rare occurrence.

But sometimes people without any cicatrix get rid of this tubercular deposit. When it has only occurred at one spot an open cavity remains, and so they go on, and live for a long time. This however, I believe, is comparatively rare; it is so common for tubercle after tubercle to take place in the lungs, and go through successive changes, that people generally do not live. It certainly does happen sometimes, that the lining membranes of these cavities become hard, secrete a quantity of mucus, and so remain during the rest of life; no farther mischief being done, pectoriloquy being always heard, and the patient only being troubled with cough and expectoration. But this also is comparatively rare.

Pneumo-thorax.—Now and then—but this likewise is an uncommon occurrence—death will take place, from ulceration extending outwards through the pleura. In cases of this description, the patient is generally seized with a sudden difficulty of breathing, and on striking the chest you find that there is a very clear sound, and, as you may suppose from the air escaping from the lungs to the pleura, the lungs become more and more collapsed. If it occur on the left side of the chest, the force of the air will be such as to drive the heart to the right side. This is called *pneumo thorax*, but, as I shall afterwards point out, it should be termed *pneumato-thorax*. I shall speak of this when I come to diseases of the pleura; but, now and then, it is to be remembered, that ulceration is not confined to the lung itself, but the pleura becomes ulcerated, or is rendered so thin that it gives way—ruptures—and then you have air and fluid in the pleura. I shall speak of that more particularly hereafter, but I must now mention it as one of the effects of consumption. In general nature prevents this, however near to the surface the cavity may be, by causing adhesions. You will recollect I mentioned generally, that when a tubercle is near the surface of the lung, the pulmonary and costal pleurae, one or both, throw out

lymph, and become glued together, so that ulceration may go on within, and yet neither air nor fluid can escape into the pleura. But now and then nature fails. A tubercle exists near the surface; the ulceration goes on; no adhesions take place; a perforation is produced by the ulcer, and the phenomenon of air and fluid in the pleura occurs.

Erratic Symptoms.—Besides those morbid appearances and those symptoms which I have mentioned as occurring in phthisis, you will find a variety of others in different patients. Some have a very great disturbance of the digestive organs; some have tenderness of the epigastrium, tenderness of the abdomen where the small intestines lie, and tenderness likewise of the liver. Some have very little appetite, but a large number have an excellent appetite, and digest and eat well to the last moment of their existence. It is very common for a fistula to form by the side of the rectum, and after death it is very common to find a considerable inflammation of the mucous membrane of the intestines. It is by no means uncommon to find the intestines ulcerated—to find a serofulous deposit in the mesenteric glands—and to find the liver more or less diseased. The French have attended very minutely to the proportionate occurrence of these different morbid affections of other parts. I believe you will find in Louis's work, a physician now living in Paris, the most accurate information on this point. It is very common to find the trachea ulcerated—to have a serofulous deposit in various parts of the trachea, particularly about the larynx. In some instances you have soreness, violent cough, every mark of chronic disease of the larynx; whereas, in other cases, there is no hoarseness—no signs of affection of the larynx or trachea, excepting a little inflammatory irritation from the excessive secretion of mucus.

I do not know that it is worth while to state these things particularly. In phthisis you will find very often an inflammatory state of the various parts of the abdomen; you will very often find fistulæ; very often find organic disease of the liver, particularly of the intestines. Now and then serofulous tubercles are found in the brain, or at least under the pia mater; but, for the most part, the head remains perfectly free.

Predisposing Causes.—There can be no question that the disposition to this disease is frequently constitutional—frequently hereditary. Those who are most subject to it are usually fair persons, with light hair, sanguineous temperament, soft skin and hair, with long pointed fingers. Their flesh is flabby, not firm, and they have large pupils of the eyes. They are fre-

quently thin and tall; but whether they are tall or not, this description of person is slender, with a long neck. Frequently, too, such persons have been subject to hæmorrhage from the nose when young. There is another description of persons subject to phthisis, who are not tall, but short, and who have not light hair and a fair skin, but who are rather swarthy, and have dark hair and dark eyes. These also have large pupils, and their skin is rather soft, and instead of having long they have short truncated fingers and nails. Their fibre, too, is lax, like the other, their muscles being flabby; and this latter description of persons generally have a tumid upper lip. There are, therefore, two descriptions of persons most liable to phthisis; both, in general, have a soft skin, soft hair, and a flabby fibre, and look pale; but one set of people, if they be not tall, are slender, and generally have light hair, a florid complexion, and are disposed to hæmorrhage; whereas the others are short, with dark hair, have a tumid upper lip, and short truncated fingers. This form of body is of course constitutional, and it likewise may be hereditary; therefore the disposition to phthisis may be said to be in many constitutional and hereditary.

A certain age is more liable to the disease than any other. Scrofula is more likely to occur in the lungs between the age of eighteen and thirty, than at any other period, in this country. When it occurs later than this, it perhaps is more frequently the result of unfavourable external circumstances upon constitutions moderately disposed to it, than of the mere intensity of the predisposition.

There can be no question that it is greatly predisposed to by bad food, bad lodging, and bad clothing. Many would escape the disease were it not for their being exposed to wet and cold, being badly protected in the way of lodging, or of clothing, and not fortified with the means of resistance to wet and cold by good food, which keeps up a good fire within, and compensates in a great measure for the unfavourable state of the atmosphere. Hence the disease is much more frequent in countries which are wet and cold than in others, and it is more frequent in countries which have cold and wet alternating with warmth, than in those which are simply cold. For example: I believe it is not so common in Russia as in many other warmer parts. Alternations of temperature, especially the union of cold and moisture, with a warm temperature, seem to have the greatest effect in exciting the disease, and to be the great predisposing cause, next to hereditary, constitutional disposition, or the want of food, clothing, and lodging. It is far less frequent in

tropical than in temperate climates; indeed, in the tropics, it is said that real strumous phthisis is unknown, or is confined to the European settlers, who bring the disposition to it from unfavourable climates. It is a disease seen more or less in all parts of the world, or nearly so, either occurring among the inhabitants, or among those who come from countries where it is very common. Some ascribe the comparative rarity of the disease—I only say *comparative*—in Russia, to the circumstance of the people having good clothing, being clad with furs and other warm materials, and eating plenty of animal food. All the inhabitants of cold climates eat a large quantity of animal food, while those who inhabit warmer regions care little about it, and live principally on vegetables. The diet of Italy and Russia is completely different. Then, to shew the effect of clothing upon the disease, it is said that in Scotland it was unknown (I suppose that is an exaggeration) before the people changed their dress from woollen to cotton. Formerly, it is alleged, that in Scotland the people were all dressed in woollen, as the Romans were; but that since they have changed it for cotton, the disease has become very prevalent. The disease is said to be the least prevalent among butchers, fishermen, and fishwomen—I mean fish-fags—the women who sell fish, and who in Scotland are called “fishwives,”—because these people eat plentifully of animal food.

When the predisposition is very strong, the most favourable external circumstances can scarcely keep away the disease. You will see a succession of persons in a family brought up with every care in guarding against cold, having good food, attention paid to the slightest indisposition, good clothing, and of course good lodging, and yet one after another, especially if they be females, become the victims of this disease. On the other hand, where the disposition is not so strong, by taking great care to avoid vicissitudes of temperature, to dress very warmly, and to be well nourished, people escape it. And if persons intermarry who have this disease in their respective families, who themselves are disposed to it, and perhaps afterwards die of it, one or both, the affection is almost sure to be transmitted to the offspring. You must have all seen instances of children dying in a family whose mother died some years before of the same disease. Where two first cousins marry together, the predisposition derived from this unfortunate mixture becomes so powerful that a very phthisical offspring is generally the result. Whoever belongs to a phthisical family should endeavour to cross the breed by marrying some one that is not phthisical,

because, although it is delightful to marry a lady delicately beautiful to all appearance, having white teeth, a fine skin, soft hair, and so on, yet misery is sure to be the consequence; the disease is almost sure to begin, and the offspring perish one after another.

Exciting Causes.—The immediate exciting cause of the disease, when one is apparent, is generally that of any common inflammation, any common cause of catarrh. Exposure to cold, more particularly cold and wet, especially when applied partially, and again, especially when the body is overheated, is the most common exciting cause. Persons with a strong predisposition catch cold from the slightest causes—from something that would be insufficient to give another individual cold; and what would be mere catarrh in one person, becomes in the other the commencement of phthisis. Sometimes tubercles have already existed in the lungs, and these merely produce inflammation in the organ; in other cases inflammation is induced in the air-tubes, and the disposition being strong, the debilitating effects of the inflammation lead to the production of the tubercles.

Whatever exhausts the body may produce this disease. When persons are predisposed to it, they will have it come on without catching cold at all, but simply from over exertion of the body, or over exertion of the mind. But where there is mental exertion, there is almost always anxiety; it is seldom that a person is occupied mentally without anxiety, and therefore anxiety may be the cause of the disease in a great degree.

There can be no doubt that the depressing passions will produce the disease. I have seen a case myself, where, in a predisposed family, an individual has become the victim of phthisis decidedly from the very time that some great source of grief occurred to him.

Powdery substances in the atmosphere have excited the disease, not simply in cases where there was a strong predisposition to it; but where the powdery dry substance is of a hard nature, such as portions of metal or portions of stone, the disease is produced almost without any predisposition being discovered. There are certain occupations in which fine particles of stone are diffused through the atmosphere, and others in which fine particles of steel are so diffused, and the persons exposed to these very frequently die of phthisis; so that in some parts of the country, where these trades prevail, few men, who work at them, live beyond forty, and many die much before that time.

It has been supposed that the disease will arise from contagion; but it is in fo-

reign countries that this idea prevails. It is believed in Languedoc, Spain, and Portugal, and the clothes of patients who have died of this complaint are there burned by the civil authorities. Morgagni, as every body knows, was so frightened at the contagiousness of this disease, that he never opened the body of a person who died of it: but that was evidently the result of a little nervousness, rather than of his better judgment. It is mentioned as being contagious by Morton, a writer on this disease in our own country; but it was not so considered either by Hippocrates or Celsus. I do not believe that it is in the slightest degree contagious. I have, like every body else practising medicine, seen hundreds and hundreds of cases of the disease, but I never saw an instance in which there was a shadow of probability of contagion. I have seen husbands nurse their wives, and wives their husbands, and I am quite sure that where the survivor has become phthisical, the proportion has not been greater than you might expect where a disease is as prevalent as phthisis. It is not uncommon for persons to fall into it in the same family where there is great anxiety. I hardly recollect a circumstance where the husband has died of phthisis, and the wife has fallen a victim to it immediately afterwards, where there has not been a predisposition to it before. I have seen so many hundreds of examples of the reverse, that I do not think the proportion is greater than it would be, if it were a matter of absolute certainty that the disease was not contagious at all.

The presence of other diseases will of course excite this. It is very common for the disease to come on after inflammation of the lungs, after severe bronchitis, peripneumonia, or pleuritis; but it is certainly very often the case that the inflammatory disease which has preceded it, has been the result of a predisposition in the region of the chest to disease at large.

Sedentary occupations of all descriptions must be unfavourable to it, because in sedentary occupations there is a want of fresh air, as well as of due exercise. Crowds, too, are generally collected together, and unhealthiness of all descriptions must be engendered. With some, the exciting cause has been great respiratory exertion, such as excessive public speaking, excessive reading aloud, excessive blowing of wind-instruments, and some have had symptoms of phthisis which have declined after giving up the flute or some other wind-instrument. The disease has frequently been excited by mercury. It is very common for us to see persons who have been in the foul wards of an hospital, and undergone a considerable administration of mercury, at the end of all this fall into a state of phthisis. Excess in venery

is likewise by no means an infrequent exciting cause. I have seen many young men die of phthisis a twelvemonth after their marriage, although they had shewn no signs of it before. You will sometimes have an abscess of the lungs—you will sometimes have an abscess of the liver making its way and producing an adhesion to the diaphragm, and of the diaphragm to the lungs, and so on—but all this is not phthisis; where, however, there is a great predisposition to the disease, this may be the exciting cause.

Diagnosis.—In regard to the diagnosis of the disease, it must be made out by the general observation of the patient—general observation as to predisposition and as to constitution. Then, again, as to the progress of the disease, whether a person has had cough for a great length of time, which has generally increased—whether there has been a falling away in flesh, and the individual has not passed the middle period of life, but is between eighteen and thirty—if these symptoms occur, and there has been phthisis in the family, you have still greater reason to suspect the formation of tubercles. If in females there be a suppression of the menses—if in males or females the ends of the fingers become enlarged, and there are frequent attacks of hæmoptysis, together with a continual cough, the case will be rendered still more suspicious. By means of the stethoscope, you may ascertain after a time whether there is a cavity or not; but in this disease the diagnosis is but too easy, after the affection has once formed.

Prognosis.—As to the prognosis it must always be bad. It must be a very happy circumstance when a person recovers from tubercles in the lungs, but you ought never to calculate upon it. It is a great blessing when it does take place, but you should never expect it.

Treatment.

The treatment of the disease must be totally different under different circumstances. Very little in general can be done after it has gone on to a certain length. We can do something then to alleviate suffering, it is true; but before it has occurred, unless the predisposition be very strong, I think that much may be done in preventing it, provided the person be in a situation that you can do what you wish.

Prophylactica.—The great mode of preventing phthisis, when there is a predisposition to it, is by invigorating the body as much as possible, by taking care that the individual shall have plenty of fresh air; go out every day; have just exercise enough without producing any fatigue; have a good portion of rest at night, and never be deprived of it; eat plenty of animal food of the best quality; take malt liquor, or a

certain portion of wine, if it can be borne;—but malt liquor is the most invigorating, and for the most part wine merely stimulates, and in most cases does harm. The state of the mind is also of very great importance, and the utmost care should be taken to commit no excess in study, exercise, venery, or any thing else, so as to do nothing that can do harm, and yet maintain all the functions of the body. The utmost attention should be paid to clothing. A large number of females in this country fall into consumption chiefly through their own fault. The poorer classes cannot dress well, cannot be expected to take that care of themselves that they should, because they have not the means; but the rich and the middle classes do every thing they can to fall into consumption. They wear hardly any petticoats, so that when the wind blows, you may discover all their beauties and see their shape. They wear silk stockings and the thinnest shoes, and so walk out; or if they do not walk out thus attired, they stand on the steps of the door, and often go on the pavement some yards before they get to their carriage. They will go from the hottest rooms without any thing about their feet; they take little sleep; have party after party every night; and then, at last, fall into a state of consumption: and neither themselves nor their friends will believe that this want of rest, and this extreme excitement, has been the cause of it; but I am quite sure it has. I think I have saved the lives of several young ladies by insisting upon their following my advice of wearing plenty of flannel—flannel drawers, flannel waistcoats, and high dresses, so as to come up to their collar-bones; at least, I have seen several who appeared to have every disposition to phthisis, but who by wearing flannel from their collar-bones to below the knees, next the skin, have passed that age at which phthisis would in all probability have begun, and have done well. I have taken care to add to this good living, making them take meat at least once a day. Many wish to make themselves look slender and genteel, and therefore they starve themselves into the bargain. You should make them eat meat once or twice a day, and an allowance of malt liquor, which for the most part is better than wine. If you can do all this, you may in many cases prevent phthisis, especially if, in addition, you can make patients use the cold shower-bath. Many cannot bear a cold shower-bath at first, but they can bear it tepid, and by degrees they can bear it cold. It was only a few days ago that I saw a young gentleman whose brother died of phthisis. He spat blood at the same time as his brother, and they appeared equally disposed to phthisis. However, in one, the disease

ran on very fast, and he died: the survivor was spitting blood continually, and had a large pupil of the eye. I prevailed upon him last summer to begin using the shower-bath, and he has done so all the winter: and the result has been that he has lost his cough, spits no more blood, and he is now a strong young man. No doubt, if he take care of himself, and commit no excess of any description, he will go on well. I do not know any means so powerful in hardening the body as the use of the cold shower-bath; but it is to be remembered, with respect to hardening, that you cannot harden every person, and that you may kill many in the attempt. Some ladies, in order to strengthen themselves, will go out of doors in the most frosty weather, and by that means often injure themselves. You may make the most delicate hot-house plant hardy by lowering the temperature gradually; but what will harden one will kill another, and what will not harden one at all, would be quite sufficient to harden another, and therefore the greatest care should be employed. Some try to harden themselves by having the window open, and they glory in having snow on their coverlet. Some can bear it, but a great number never could bear any thing of the kind. Still, I am sure, it is proper treatment to harden people as much as can be borne.

You find, however, that some persons are so disposed to an inflammatory state that it is not at all admissible to give them wine, beer, and meat. They may be of so inflammatory a disposition, that the utmost you can do is to clothe them well, make them guard against catching cold, and order the shower bath. Some persons are so disposed to hæmorrhage—hæmorrhage from the nose, and then hæmorrhage from the lungs—that nothing stimulating can be allowed. There are such cases; but in the greater number of instances I know that by fortifying the constitution well, adjusting the means used to fortify it according to the state of the constitution, you may do great good.

When the predisposition is very strong, it is not only necessary that the patient should most carefully avoid catching cold, by wearing warm clothing when he is out of doors, and by avoiding all danger arising from wet feet, but the temperature of the room in which he is should be prevented from falling too low. In many cases it is necessary that the bed should be warmed; but others not so delicate as all that should have a fire in the room, either when they go to bed or get up—once in the twenty-four hours, for the purpose of thoroughly warming it. Some persons are so delicate—so disposed to phthisis—that we can hardly allow them to go out even during

the winter, and in their rooms a certain degree of artificial temperature must be maintained; but these are cases where the predisposition is extreme, and the debility very great.

It is also of great use, where there is a strong predisposition, to send patients to a warmer climate than our own, and one of the best places to which they can be sent is the West or East Indies—to a thoroughly warm climate. If that be too far, one of the best places is the south of Spain, or the south of France. Many parts to which people are sent are very objectionable. Lisbon, for example, is very cold in the winter, and both Venice and Naples have high mountains in the neighbourhood, and therefore are not good. If you cannot send patients to the East or West Indies, certainly the south of Spain and the south of France are among the most proper places. But many cannot go even there, and for them the warmer parts of England are the only situations left. I need not mention that parts of Cornwall and Devonshire are the most suitable, and I believe Penzance is particularly so. Nearest to London, one of the best places certainly is Hastings. Many persons near London have an idea that if, instead of living in London, they go to Brompton, they are more protected from the disease; but I do not know whether there is any thing in it. I have heard practitioners found fault with for allowing their patients to live here, and not sending them to Brompton. It has a great name, but I do not know whether it deserves it. But all this must be done before the disease is fully formed: for when it is once established, I think it the greatest cruelty imaginable to send them abroad. It is horrible to see the grief it occasions, and the patient still dies of consumption. To send them away from home, and suffer all the misery of the journey, is not only very absurd, but very cruel. It is much better, when the disease is once formed, to allow patients to remain at their own home, where there is every comfort around them.

Antiphlogistic remedies.—When the disease has formed itself, the treatment must be very different under different circumstances. You generally have to subdue or mitigate inflammation. There are frequent attacks of pleuritis, bronchitis, and peripneumonia. You commonly find the pleuræ, or the lungs, or both—in the lungs I include the air-cells and bronchiæ—in a state of inflammation. Persons are continually seized with violent stitches in the side, and it is necessary to take away a little blood—four or six ounces, sometimes more, or to cup the part, or to blister it. You find the blood buffed, and you have to treat the case for a time as one of inflam-

mation of the chest, but with little power of the constitution. Under these circumstances, of course it is necessary that the diet should be low. If patients be seized with hæmorrhage, it is often necessary to treat them in the same way: it is generally necessary to bleed the patient to some little extent, and to keep him on low diet. When there have been attacks of inflammation or of hæmorrhage, it is necessary for some days to pursue antiphlogistic diet; but these may all subside, and you may have recourse to nutritious diet again, or now for the first time, if not before. It is, however, right not to take alarm at every pain in the side which a phthisical patient may have, for many such attacks will go away without strong antiphlogistic measures, and many will go away from a blister, or the application of a mustard poultice, which is one of the best things. If, however, that will not remove it, it is requisite to bleed, and to treat it in the common antiphlogistic manner.

Diet.—Supposing, however, that there is no inflammation to subdue, no hæmorrhage, and the patient is free from pain, and has been so for some time, then you have to support him as well as you can, and to lessen the irritation. It is often indispensable to give meat and malt liquor. You see many persons who are spitting up in phthisis the better for having meat. Wine has a tendency to stimulate, and therefore it should not be given; but ale will often be proper. In a great number of cases, you have to consider that the patient is just in the same situation as an individual having a large abscess in the extremities, which, from pouring forth an immense quantity of fluid, has exhausted him. In that case, you must allow meat and beer, in order to support the patient, and administer opium to lessen the irritation; and in phthisis the treatment must be conducted precisely in the same way.

Tonics—In this state of things it is very useful, when there is no inflammation, no hæmorrhage, to give tonics; but of all tonics, iron is by far the best. The use of what is called *Griffiths' mixture* is well known. There was a Dr. Moses Griffiths, who made a mixture of iron and myrrh, which is a very good form; but the myrrh is nauseous, and after making a number of trials, I am satisfied that the iron will do as well without the myrrh as with it. The sulphate of iron answers exceedingly well; and when you recollect how often there is cough in the disease, out of proportion to the regular irritation that takes place, you may see that the iron may relieve the cough even to a greater extent than it supports the constitution. Many cases, I mentioned before, which have been supposed likely to end in phthisis, have given way to the

exhibition of iron. If the sulphate purge the patient too much, or excites the pulse, the carbonate may be given, which is rather the milder form of the two. If you exhibit two or three grains of the iron three times a day, you will see patients gain strength up to a certain point, and their cough will diminish. The relief, it is true, is only temporary, but you do good for a time, and it is your duty to protract life without regarding whether it is useful to the patient or not. We are to follow the invariable rule of saving life or protracting it, whenever it is placed in our power to do so.

In this state of things, though you cannot use the shower-bath, you may do great good and produce great comfort by sponging the patient well with vinegar and water: you may even check the hectic sweats, better by vinegar and water, cold or tepid, than by any other means. When, before the disease is formed, persons cannot bear the cold shower-bath, they can bear it tepid; and when the disease is fully formed, a tepid bath is frequently borne, though patients cannot bear the cold bath. Tepid sponging is very beneficial, and it is better, perhaps, if vinegar be mixed with the water; at least, so it is said. Many persons, when they have expectorated pus, have, from tepid sponging, come to bear cold sponging, and have found the greatest relief from it; that is to say, when hectic heat is upon them, they find it very comfortable: but, as I have mentioned many times, the feelings of the patient should always be consulted.

Anodynes.—Among the means of lessening irritation, opium is one of the very best. There are other things, I need not say, such as hyoseyamus, conium, and extract of lettuce, all of which do a certain portion of good, and very often they are more eligible than opium, because the latter may disagree. I believe the best preparation of opium is muriate of morphia, because its unpleasant effects are seldom more than one—namely, constipation—and even that is often a good thing in phthisis, because in phthisis there is generally a disposition to relaxation of the bowels. A quarter of a grain of muriate of morphia is equal to a grain of opium, and is more certain in its operation than any other form of that drug. A solution of it is very cheap.

Inhalations—You may sometimes lessen the irritation by making the patient inhale various things, by having a vessel three parts filled with warm fluid, and making a patient inhale through it; that is to say, you must have two tubes, so that the air may pass through the body of the fluid. The tube which admits the air must go to the bottom of the liquor, so as to convey the atmosphere down, and the tube to be inhaled from must be fixed above the liquor.

The agents which have been tried chiefly, are, first, a very minute quantity of iodine mixed with hydriodate of potassa; and, secondly, chlorine. I have seen more mitigation from the chlorine than the iodine, but I have never seen a case cured: I have used them both perseveringly, but I never saw a case of phthisis cured by these means, and I do not believe that a case ever was cured. I have known a single drop of tincture of iodine, put into a pint of fluid, produce great irritation; but chlorine is borne much better: the mitigation afforded by it, however, is but temporary. The mode of using it is this:—into three-fourths of a pint of water you may drop four or five minims of saturated solution of chlorine. It is best to begin with one or two minims, and increase the quantity gradually, as the patient can bear it; but if you at last arrive at a quantity which he cannot bear, you must then desist, and go back to what he can bear.

Some have recommended the exhalations of tar. Tanners, as well as butchers, are said to escape the disease; and I have employed the liquor from tan-pits, in which there is an infusion of oak-bark. I have made people inhale it, and some have found considerable relief; others, however, have found the smell so unpleasant that they could not go on with it. I have not used it long; but as to its curing the disease, I should imagine that is out of the question. I believe that no means whatever will effect so desirable a purpose.

Removal of urgent symptoms.—Besides the great indication, when phthisis is once established, to subdue inflammation if you can, whether it occur in the form of pleuritis, or bronchitis, or peripneumonia; besides the indication, on the other hand, to support the strength by nourishing food and tonics; besides subduing irritation, which is a third indication, by narcotics; you will find it necessary to attend to another indication, the removal of urgent symptoms of various kinds.

You will continually find a person sweating so profusely, that his strength is thereby greatly diminished, and this may often be subdued by washing him all over with tepid vinegar and water several times a day, or by the exhibition of sulphuric acid, and again, sometimes by superacetate of lead. You will have frequently also to subdue another evacuation, which is purging. This, of course, is to be accomplished chiefly by astringents and opium. Unfortunately, the more you subdue one evacuation, the more you increase the other: frequently when you check the sweats, the purging becomes more intense, so that it is safe while you are lessening the sweating by tepid ablution—vinegar and water, for ex-

ample—to give astringents, lest diarrhœa should suddenly begin. Diarrhœa is one of the most tiresome symptoms in consumption, and very frequently astringents and opiates do not succeed, on account of the inflammatory state of the mucous membrane, and yet the patient is too weak to enable you to apply leeches, and suffers so much altogether that it is very painful to apply blisters. In many cases, fomentations or poultices of bran applied to the abdomen will be as good means as you can adopt. Frequently the largest doses of opium, such as will produce great stupor, and the largest quantity of astringents, such as almost overload the stomach, have no tendency to check the diarrhœa. For a long time they may succeed, but at last, in most cases, the diarrhœa becomes so severe and obstinate that they lose their effect. It is remarkable to see what a large quantity of astringents and opium you may give with little or no benefit. However, we must do our best, and astringents and opium are certainly the best modes of checking the diarrhœa. Frequently there is ulceration of the intestines, and among the astringents you find sulphate of copper answer better than any other. It has a tendency to produce sickness, but that may be subdued by hydrocyanic acid. If you exhibit sulphuric acid, it is generally necessary to guard it by laudanum, on account of its acrimonious qualities when given by itself, tending to increase the affection of the bowels.

Empirical Treatment.—Certain remedies have been boasted of as capable of curing consumption, but there is no reliance to be placed on any of them. You are continually asked about the propriety of Iceland moss, and things of that description: there is no harm in them; on the contrary, they are good so far as they are nutritious and bitter, and are very proper things to be given, but there is no hope of saving a patient by them. You will read accounts in which it is stated that a large quantity of vinegar has cured the disease. Some persons give about seven ounces of vinegar in the course of twenty-four hours, mixed with seven ounces of water, and sweetened with two ounces of refined sugar; but fair trials have been made with it without success. The balsams have also been recommended, but sometimes they heat the system exceedingly, and increase the inflammatory state. Myrrh has been recommended by some, but I believe it does no more good than any other tonic. We have also the sulphate of copper strongly recommended to us, and it does alleviate the symptoms. I have seen it, I think, when guarded by opium, not only check the diarrhœa, but diminish the copiousness of the expectoration: it has, however, no specific

virtue. Some have recommended us to give a person an ague; but so many persons die of consumption who have ague, and consumption is so common in aguish parts, that there is no reliance to be placed on this, and it would be great cruelty to give a person another distressing disease, such as ague, for the mere chance of doing good once in a thousand cases.

Little more can be done in this disease than to lessen inflammation, support the strength, lessen irritation, and subdue urgent symptoms; for, after all, persons generally die of the complaint. The disease goes on progressively, and we can lessen suffering, but that is all, though, as I have said, no doubt the disease may be prevented by great care.

Comparative Mortality from Phthisis.—It is said by Dr. Young, in his work on Consumption, which is a sort of Bibliographia Physica—for he refers to every work written previously to his own on the subject,—that one-fourth of the inhabitants of Europe die of phthisis. Years ago it was calculated that a thousand persons died of the complaint in Great Britain every year; but, in Europe altogether, we are told by Dr. Young—and I dare say we may depend pretty much upon his estimate—that one-fourth die of the disease. The mortality in this country is greater than in Paris. Whereas one in four die of this complaint in Great Britain, one in five only die in Paris, and at Vienna only one in six.

Elongation of the Uvula mistaken for Phthisis.—The symptoms of phthisis have very often been mistaken for real phthisis, when they arise merely from elongation of the uvula. This is a little point worth knowing.

When the uvula is elongated—hanging from the pharynx—it sometimes produces constant cough, and this leads to a constant expectoration of mucus, and in some cases to emaciation: it now and then happens that extreme emaciation has been the consequence of an elongated uvula. Patients, from the constant cough and expectoration, have become emaciated, the tongue has become white, flying pains have taken place in the chest, loss of appetite has occurred, the pulse has become small and unequal, frequently a pain has been felt in the larynx, constant efforts being made to expel the mucus, all of which has arisen from an elongated uvula, and therefore it is right, whenever you are consulted by a patient labouring under these symptoms to look into the pharynx.

Treatment.—The complaint may be remedied presently by slipping off the lower half of the uvula with a pair of scissors. The pain is but momentary; there may be a little bleeding, but the operation is perfectly safe. It is very seldom that such

severe symptoms will occur, I imagine, as to be mistaken for phthisis, but sometimes such a circumstance has taken place. Very often, however, persons have a tiresome cough, which has been mistaken, so that blisters have been applied to the chest when the symptoms have arisen from nothing more than an elongation of this part. In regard to local applications, the best are those which unite astringent with stimulating properties; but in cases where these fail, the operation of curtailing the uvula should be had recourse to.

SOME ACCOUNT

OF THE

DISEASES USUALLY TREATED IN MONTSERRAT.

BY JOHN BADHAM, M.D.

Lately of that Island.

To the Editor of the Medical Gazette.

SIR,

As it is probable that many of your readers will not be displeased at obtaining some general idea of the diseases most apt to prevail in the negro population of the West Indies, without putting themselves to the trouble of consulting those various works on tropical diseases which are so seldom included in a course of general medical reading by British practitioners, I have ventured to throw together a few recollections on the subject. The place in which these observations were made is the island of Montserrat. The time during which they accumulated was about three years, and the practice of which they are the result extended over a negro population of about 4000, augmented by the medical charge of the detachment hospital in that island.

1st, Fevers. Of these, towards the close of the year, a good many occurred in particular situations, and of a malarial origin. The common type was tertian, with occasional cases of quartan, and these fevers were so exactly confined to particular districts that we used to distinguish them by the names of the localities where they prevailed, as the Old Road fever, Bransby's fever, &c. It was often difficult to cure them even while they observed the regular type, which they soon ceased to do. In some cases, indeed, we were fortunate enough to cut

them short by vomits, particularly by sulphate of zinc. I once bled in the cold stage, but from the alarming collapse of strength in that case I never ventured to repeat it in other cases, though the patient fortunately recovered. These fevers frequently degenerated into a remittent form, complicated with various visceral affections, chiefly hepatic, for as to splenic ones I do not distinctly recollect any.

As to the less tractable cases, we generally at last got them out of the sick house, but they often became cachectic, quite incapable of active exertions, and loiterers about the yard, till some visceral complication carried them off. Sometimes convalescence would follow removal to a mountainous district, but I also recollect other instances in which such removal was not attended with recovery of health. I saw no form of continued fever.

2d. Exanthematous fevers. As the negroes are vaccinated, I may say generally, though not universally, we had no small-pox. Measles occur, but no cases ever fell under my charge, nor am I able to say whether the disease occurs in this warm climate in a mitigated form. Scarlatina during one year prevailed extensively, and occasionally with great severity. The negro's skin, under fever in general, particularly eruptive fever, assumes a peculiar leaden hue. The lips in the hot stage are bright red; in the cold, perfectly colourless. The throat was often extensively ulcerated without any eruption on the skin at all: this happened in my own case: I recovered after losing a portion of the soft palate. I may here mention, that although this disorder is generally considered to be one of those which absolutely liberates the party from a second attack, I am myself an exception to that general, but, as I have reason to know, not infallible security. I had undergone this disease in its most alarming form, during my childhood, in the north of Italy. There was nothing peculiar in our treatment of ulcerous angina: we used the chlorides and muriatic acid, and myrrh, &c. &c. for gargles, and applied the nitrate of silver in solution to the sloughs, which were slow in separating, by a camel's hair pencil. Quinine was sometimes, and beneficially, had recourse to, even before the febrile heat had subsided, for there were often cases in which the pyrexial

state appeared to be compatible with extreme debility. One very severe case of erysipelas was brought on by wounding the foot with an acacia thorn; violent inflammation extended up the whole extremity; it was treated by incision and the usual auxiliaries, but the brain became early affected, and the patient died. This was the second case I had treated of fatal erysipelas consequent on a thorn puncture. The other took its origin from incautiously gathering a common moss rose in England. In both cases effusion of serum into the ventricles was found after death, and the vessels of the dura mater congested.

3d. Inflammatory affections. Accretions of a fibrous structure, spreading over the conjunctiva of the eye, and originating at the caruncula, but not always the result of express conjunctivitis, were exceedingly frequent, and were usually removed by the knife or scissors. When the conjunctiva was merely affected with common inflammation, the nitrate of silver, of various degrees of strength, was the ordinary and effectual remedy.

I saw no cases of phrenitis without original fever, although the heat of the sun and habits of intoxication might perhaps lead strangers to a different expectation; but many cases of delirium tremens have fallen under my charge, and some of great severity. The result of the cases I treated was generally satisfactory: one or two, however, died: in one case, that of a man addicted for many years to dram-drinking, the brain was found somewhat softened, and a general effusion, both external and internal, was observed, and the liver was hypertrophied, with ramollissement of the mucous membrane throughout the alimentary canal. In cases of delirium tremens, opium and stimulants, including even the concession, to a certain extent, of the very stimulus of alcohol which had produced the disease, (and which could not be safely withdrawn) were the established practice. In one very memorable instance in the white population, (it was that of an individual whose habits of life had exposed him to a frequent relapse into this disease) we were led to make a trial of strychnine. The remedy succeeded, and we were able to carry it to the very large dose of one grain twice or three times a-day*.

* I have no experience of strychnine in paralytic affections, but from trials made of it by my

The negro frequently suffers by inflammation of the various parts contained in the thorax. He is subject to pleurisy and peripneumony, and he bears large bleeding generally ill. I have found the lungs here, as usual, congested and hepatized, but I have also found them atrophied, and shrunk up. I have not met with purulent depositions either in the form of vomica or empyema, though I believe these results often take place. I consider phthisis to be a much less uncommon disease than is usually supposed among the negro population; and from what I have seen or can learn, its fatal result is not retarded by difference of temperament or climate. The consumptive negro, like the European, falls into hectic, and dies tabid and emaciated, with blanched lips, after continued expectoration of matter of various appearance, sometimes prolonged through a very extended period, sometimes during a very brief one, before the disease proves fatal†.

I recollect no cases of laryngitis; but the parotid swelling I have treated, and have witnessed, in one or two instances,

father in the Royal Infirmary of Glasgow, in which the most cautious augmentation of the dose was found hazardous, and in one instance produced tetanic spasms, I should hesitate about using it again in such a disease as delirium tremens.

† Perhaps this note will be of more interest to the profession than the text to which it refers. I will not venture absolutely to consider myself as a person cured of consumption by a voyage to, or residence in the West Indies; but the following facts will not be read without some encouragement to others.

I was sent promptly from England, four years ago, after a full deliberation of my case by my father and his medical friends, in a vessel about to sail for Trinidad, and without any doubt as to the phthisical character of my disease. I was already in a state of great debility, with a quick pulse, cough, and what was considered to be unequivocally purulent expectoration. I had lost one parent by phthisis; and subsequently to my departure, another of my family, who most resembled me in external form, and whom I left in perfect health, fell a victim to this fatal malady. I had also, when eight or nine years old, had the narrowest escape from death by pulmonary vomica: of course nothing can be proved, but as far as a solitary instance, occurring under the eyes of medical men, and in a medical family, may afford encouragement to others, it would be wrong to withhold this communication. The removal of my symptoms took place in the progress of the voyage itself, having begun in the warm latitudes. It is certain that the ancients had confidence in sea voyages in phthisis: *Ægyptus petitur non propter se sed propter longinquitatem navigandi*. A voyage from Italy to Egypt was a much shorter affair than from Britain to the West Indies, and implies much less considerable difference of temperature. I shall be very happy to give the fullest information of my case to any person whose apprehensions for themselves or others may make it interesting.

its well known metastasis to the testes. These latter organs, indeed, are exceedingly liable in that climate to a chronic form of enlargement familiar to every practitioner. Sometimes this enlargement is seated in the cellular substance only; at others it affects the whole gland. Such swellings sometimes become of an amazing size, and are generally without pain: I have seen them as large as a cocoa-nut.

Judging from my own experience, I should say the mucous membrane of the alimentary canal is in the West Indies much oftener affected with inflammation than the serous membranes. Of acute peritonitis, I never saw a case, either connected with the puerperal state or otherwise; nor have I seen enteritis, meaning by that term inflammation of the serous passing into the muscular coats of the intestine, with various subsequent degeneration of tissue. I have met with cases of dysentery, but never saw reason to attribute that disease to malaria, as in the East Indies, nor have I found it communicated from one person to another. The whole negro population is very subject to diarrhoea, and this description of bowel complaint may be reasonably attributed to the change of diet which the negro so frequently undergoes. At the crop season the sugar-cane is devoured in large quantities, while at other seasons the common food is salted cod or herrings, (four per week!) with Indian corn meal, more or less liberally bestowed according to the liberality of the different estates, but never too abundantly. It is impossible, in fact, that any negro can live on his allowances: he adds, therefore, something from his own cultivation, (for every negro has a small patch of ground) as a sort of subsidy for his meagre and stinted rations: he grows sweet potatoes, yams, and cassada, of the pressed pulp of which a bread-like oat-cake is made. The acid fruits—tamarind, for instance—is not grateful to the blacks, unless the condiment of sugar be added, without which these productions, so agreeable to the European, are useless to him: for the same reason, though he can get limes, he never drinks lemonade. A negro is permitted to consume as much of the crude cane, and drink as much of its juice (as it flows from the mill in which it is crushed, into the boiling house) as he likes. This happy period, however, extends only from January to

July. New sugar and water is, when he can get it, his favourite beverage.

The children are very subject to worms. In place of supposing, with the French pathologists, that worms are always the result of a previously disordered state of the mucous intestinal membrane, I would believe them to produce that state, and to constitute not only an original and independent, but a very formidable complaint, producing death sometimes by mere accumulation. I have opened many children who have died of worms. Such children have had large tumid bellies and atrophied extremities: a vast colony of worms within has been plainly nourished at the expense of the constitution. In one instance, an ailing child, about eleven years of age, died suddenly. I was called, under the sudden alarm, and on opening the body I was struck by the disgusting sight of almost the whole of the small intestines occupied by *Lumbrici* crawling about in every direction. It is not to be concluded by this statement that such cases have been neglected, or do not attract sufficient attention; on the contrary, we are in the continual habit of employing anthelmintic medicines, and usually with the greatest success. An electuary of cowhage, with molasses, is kept ready for use on the different estates, and is given in repeated doses for a week, after which two or three active purges with castor oil. In more obstinate cases, the French worm grass, a plant of the island, is frequently administered with success. When adults are the subjects, which is far from uncommon, spirit of turpentine, with castor oil, is the medicine in which we place the chief reliance.

The cholera I have treated in the West Indies is that of Sydenham—merely vomiting and purging of bile, with occasional cramps, and to be treated by opium and calomel. In speaking of bowel complaints, I may observe that hernia is extremely common among the negroes; I have in several cases found it necessary to perform the operation for its relief, though in most the taxis answers. Ruptures of large extent remain irreducible, but the patient complains of no inconvenience except from its unwieldy size.

Of the colic, or dry belly-ache, which some practitioners continue to ascribe to lead, derived either from the rum or the water drunk (in the former attributed to

the passage of the spirit through the worm in the distillery; in the latter to the cisterns or tanks), I wish to observe, that I perfectly agree with Dr. Musgrave, of Antigua, that the dry belly-ache may be otherwise incurred, and is frequently found where no lead could have existed, or its presence even be suspected. On this subject Dr. Musgrave's paper ought to be conclusive to every unprejudiced mind. I have myself known the disease to prevail in a mountainous estate several miles from the town, where no rum could have been purchased, and there was none on the estate itself; yet, in the course of one week, four or five cases of this disease occurred, of various degrees of severity, while the neighbouring properties were perfectly exempt. As to tank water, fresh springs of the purest element abound every where in this lovely colony (which might be considered as the Montpellier of the West Indies.) I have therefore attributed such cases of dry belly-ache rather to the chills to which the negro is so often exposed, by the night dews precipitated on a body perhaps heated by previous labour, or voluntary exercise—such as attendance on a wake (a festive funeral), or the merry Bangle dance. I found the warm bath always useful. We generally cured our patients by the croton oil, taken every four hours in two-minim doses, with six grains of the extr. hyoscyami. When once the bowels were freely opened, the disease forthwith ceased. Bleeding and mercury, which constitute the more usual treatment, we only occasionally adopted.

The last of the abdominal complaints which I shall mention (although it may be rather termed a gastric one), is the well-known propensity to *dirt-eating*, which, though constantly denied by the patient himself, is a well-known fact. The indulgence of this propensity produces a much more marked appearance in the countenance than worms; there is a more haggard and pinched look of the features. Cases of dirt-eating are however attended, like worms, with tumid bellies and atrophied extremities. The thorax also has a peculiar lean appearance, as if the ribs were only covered with the common integuments. I should also say, that few cases of dirt eating continue long without serous infiltration into the lower extremities, or, which is very common, into the cellular

membrane of the palpebræ. On inspection after death, the mucous membrane is found softened, and so is the muscular coat of the intestinal canal generally, and both quite without colour. No curative indication can be followed unless it be placed utterly out of the patient's reach to gratify this strange propensity, in pursuit of which children are known to pick the crevices of the floor. I knew one child effectually cured by being confined in an empty hogshead, barred with some cross sticks at the top. The denied ailment is often detected, I may mention, by examining the boy's mouth, where frequently small remains of his last repast may be seen on the inside of the lips. When confinement has been effectually administered, bitters, and preparations of iron, are the best remedies.

I shall here conclude, for the present, with a word or two on ulcers; their frequency among the negroes is known to every body. Sometimes half the sick of an estate are laid up with these troublesome affections. I may say they have all a constitutional origin, and that local applications, unless as protections, are useless; excepting, perhaps, a lotion of the oxymercurate of mercury, or the occasional use of the chlorides in solution. Negro ulcers may be divided into two classes, as far as difference of cure may prove a difference of character. Some yield rapidly to calomel and opium, together with a suitable change of diet (from salt to fresh meat and vegetables); while others, in addition to a better dietetic, absolutely demand the employment of wine and quinine, and these, too, very liberally given. Mercurials in this latter, or irritable ulcer, are quite injurious; whereas, in the former, I have seen the sores rapidly heal as soon as the constitution comes under the influence of the remedy, and this, too, in ulcerations of a most extensive nature. It is wonderful what the mere change of diet, in the negro, will produce in various diseases to which he is subject, when aided by wine and bark. There is an ulcer which the cunning negro produces sometimes, in order to avoid labour; it is accomplished by placing a small copper coin, called a dog, on the part they wish to affect, and tying a tight bandage over it. In this manner an ulcer is soon procured.

In a future communication I shall mention what I have seen of diseases void of fever, spasms, and convulsions,

and recount, perhaps, a few singular cases in black midwifery, not forgetting a remarkable one in which the pains of parturition were suspended by the patient's apprehension of Obeah, or witchcraft, and restored by appearing to enter into the delusion, and hitting upon a device to put an end to it.

Workshop, Notts, April 27, 1833.

ON THE PATHOLOGY
OF
DISLOCATION OF THE SHOULDER
JOINT*.

By PHILIP CRAMPTON, M.D. F.R.S.

Surgeon-General to the Forces in Ireland, &c.

THE *treatment* of dislocation of the shoulder joint has in all times engaged much of the attention of practical surgeons. The *pathology* of the affection, however (on which alone a rational mode of treatment can be founded), has been but sparingly illustrated. In the year 1810, we find that excellent and experienced surgeon, Mr. Hey, of Leeds, lamenting that "the opportunities of dissecting the shoulder joint in a state of dislocation are so rare, that we still remain ignorant of the precise nature of the injury done to the several parts concerned in ordinary cases." In fact, at the period when Mr. Hey wrote his *Observations on Surgery*, there was, I believe, but one case on record in which the actual state of the joints in a recent dislocation of the shoulder joint was described and delineated; and even this case is deprived of much of its value, from the confused manner in which it is described, and from the very imperfect plate with which the description is accompanied; neither was the case, strictly speaking, a recent one, as eighteen days had elapsed between the reception of the injury, and the examination of the joint after death; and during this period the parts seem to have undergone considerable changes, both in their structure and mutual relations. The celebrated monograph of Professor Bonn, contains, I should suppose, all the information respecting the pathology of dislocation of the shoulder which could be brought together up to the year 1782. He gives the anatomy of several cases of unreduced dislocation of the humerus, but the most recent is of two years' standing; these cases, therefore, leave the question as to the "pre-

cise state of the parts in *recent* dislocation," and the obstacles which are opposed to reduction, untouched. Such, I believe, was the imperfect state of our knowledge on this subject, when Sir Astley Cooper, whose talents and industry, aided by a vast experience, have illustrated so many important points of pathological, as well as practical surgery, published his account of the dissection of two cases of recent dislocation of the humerus. To cases so universally known, it cannot be necessary to allude more particularly than to state, that both were instances of dislocation downwards, or "into the axilla,"—that, in the first case, "the capsular ligament was torn on the whole length of the inner side of the glenoid cavity, which (rent) would have admitted of a much larger body than the head of the os humeri through the opening. The tendon of the subscapularis muscle was also extensively torn," but the tubercle on which the supra and infra spinatus, and the teres minor muscles are inserted, was not (as in Mr. Thompson's case) torn off. In the second case, in which dislocation had existed (unreduced) for five weeks, the capsular ligament had given way in the axilla between the teres minor and subscapularis muscles: the tendon of the subscapularis was torn, though, at its insertion, all the articular muscles, but particularly the supra-spinatus, had been more or less lacerated, as it would seem, in the attempts which had been made at reduction. Sir A. Cooper found that "the resistance to reduction (even after death) was such as he could not by himself overcome; he divided one muscle after another, cutting through the coraco brachialis, teres, major and minor supra-spinatus muscles, but still the opposition to his efforts remained; he next divided the deltoid muscle, and found that the supra-spinatus muscle was his great opponent, *until he drew the arm directly upwards*, when the head of the bone glided into the glenoid cavity." To these interesting cases, illustrating as they do so many important points connected with the management of dislocation of the humerus downward, or into the axilla, I am happy to have it in my power to add two additional ones which have fallen under my own observation; one of a recent dislocation downwards, and one of a recent dislocation forwards under the pectoral muscle, on the ster-
nal side of the coracoid process.

* From the Dublin Journal, slightly condensed.

CASE I.—Anatomy of a recent Dislocation downwards.

In the year 1808, a labouring man was brought into the County of Dublin Infirmary in a dying state. The persons who carried him stated that he had been engaged in digging under the foundation of a house that had been burned, that a part of a partition wall fell upon him, and that they had found him with his head buried under the rubbish. The man did not survive more than a couple of hours. On examining the body eighteen hours after death, it was observed that, in addition to the injury of the head, which had proved fatal, the right humerus was dislocated into the axilla. To this part I directed the whole of my attention, assisted by my lamented friend and colleague the late Mr. Dease; and in the presence of some of the other surgeons of the hospital, I made a careful dissection of the joint previously to reducing the dislocation, and was so fortunate as to obtain a drawing of the parts, executed on the spot, by a distinguished artist. On removing the integuments of the axilla, the cellular membrane, which was extensively ecchymosed, formed a kind of cap, closely embracing the head of the os humeri, which, when the axilla was

cleared, was seen lodged on the inferior costa of the scapula, or rather on its neck. The head of the bone, in escaping from its socket, had pushed the *teres minor* downwards, and burst through the lower part of the subscapularis muscle, some of the fibres of which closely embraced the neck of the bone, while the bulk of the muscle was pushed upwards, and detached from the inner surface of the scapula. The neck of the humerus, therefore, was in some degree embraced by the divided fibres of the subscapularis muscle, while a portion of its head rested on the neck and part of the venter of the scapula, without the intervention of any muscular substance. The short head of the biceps, and the *coraco brachialis*, were forced to describe a curve outwards over the neck of the humerus on the sternal side, while the long head of the triceps crossed the neck of the bone obliquely on the dorsal side: this strangulation of the head of the bone, by the surrounding muscles, was made most apparent when extension was applied to the fore-arm. The biceps and triceps seemed then to close behind the head of the bone, and interpose themselves between it and the glenoid cavity. The tendon of the long head of the biceps remained in its groove, but the sheath in which it runs was partially ripped up.

FIG. 1.

The capsular ligament was completely torn from the lower part of the neck of the humerus to the extent of more than half its circumference, the torn edge appearing like a crest over the head of the bone. The great nerves and blood-vessels of the arm were forced to describe a curve backwards, by the pressure of the head of the bone which was in contact with them. But the greatest injury had been sustained by the "*articular muscles*," as they have been called, which lie on the back of the scapula. The tendons of the supra-spinatus, the infra-spinatus, and the teres minor, were completely torn off from the humerus, carrying with them, however, a scale of bone, which was ascertained to be the surface of the greater tubercle into which they were inserted.

In order to ascertain the nature of the obstacles which oppose the reduction of the dislocated humerus, the scapula was fixed, and the arm being raised to nearly a right angle with the body, extension was slowly applied to the arm by pulling at the wrist. It then appeared, that so long as the hand was held *supine*, the head of the bone remained immovable, the chief resistance appearing to be caused by the closing of the biceps and triceps behind the head of the bone. The muscles on the back of the scapula being detached from the greater tubercle could of course afford no resistance, but on turning the hand into the *prone* position, and giving a motion of rotation inwards to the whole limb, the extension being still maintained, the head of the bone glided easily into its socket.

The appearances observed in this case are nearly identical with those which are described by Mr. Henry Thompson, in the Medical Observations and Inquiries, while they differ materially from those which were found by Sir Astley Cooper, establishing an important fact, which indeed might have been inferred *a priori*, that in *apparently* similar dislocations of the humerus, there may be very different *kinds* as well as *degrees* of lesion, and consequently very different causes of resistance to reduction.

In Mr. Thompson's case, as in mine, "the head of the bone was found lodged on the inside of the neck of the scapula, between the subscapularis and teres major muscles," but during the eighteen days which had elapsed since the injury had been received, the cellular substance

of the axilla had formed a kind of capsular ligament, "which embraced the head of the bone, and contained a small quantity of mucus resembling synovia."

In Mr. Thompson's case "the capsular ligament was completely torn from the whole circumference of the humerus;" in mine it was detached to the extent of more than half the circumference. In both cases "the attachments of the tendons of the supra and infra spinatus muscles were torn off, with the part of the bone they were inserted into."

In both cases "some fibres of the subscapularis muscle embraced the neck of the bone."

In Sir Astley Cooper's cases, on the contrary, although the tendon of the subscapularis was torn through, the supra and infra spinatus muscles retained the connexion with the greater tubercle; and "until this muscle was relaxed, by raising the arm, the humerus could not be reduced by any efforts which he (Sir Astley) could make."

The following is an instance of primary dislocation forwards, in which the head of the bone is thrown at once in the neck of the scapula, without previously passing into the axilla. I believe there is no dissection on record of a *recent* dislocation of this kind; there is, however, a specimen of one which had been long dislocated, in the museum of St. Thomas's Hospital.

CASE II.—*Anatomy of a recent Dislocation forwards.*

James Wilson, aged about 30, fell into a lime-kiln in the immediate neighbourhood of the County of Dublin Infirmary, while the lime was still burning. He was drawn up by ropes; but just as he reached the top of the shaft, the rope broke, and he again fell to the bottom, a distance of about fifteen feet, on the ignited stones. As soon as he was extricated from this dreadful situation, he was carried to the Meath Hospital, when he received from Mr. McNamara, who happened to be on the spot, every relief of which his miserable situation was susceptible. It appeared, on examination, that in addition to several extensive burns and lacerations, there was a dislocation of the humerus, under the pectoral muscle.

Mr. McNamara (without assistance) reduced the bone by merely drawing the arm gently forwards and downwards with one hand, while he pushed

the head of the bone towards the glenoid cavity with the other. The poor man died in the course of the day, from the conjoint effects of the burn and the fall. Eighteen hours after death the shoulder joint was dissected by Mr. McNamara, from whom I take the description of the appearances, with the advantage of having the preparation before me while I write.

The dislocation was unattended with the rupture of any muscle, or the separation of any tendon from its insertion into the bone. By a slight effort the dislocation was reproduced, and the pectoral muscles being removed, the polished head of the bone was now seen lodged on the cervix of the scapula, at the root of the coracoid process, but extending nearly as far as the notch in the superior costa: it had passed out through a rent in the capsular ligament, over the upper edge of the tendon of the subscapularis, detaching this muscle from its connexion (which at this point is but slight) with the inner face of the scapula, and pushing its fibres downwards, so that they formed a curve which partly embraced the neck of the humerus. The supra and infra spinatus mus-

cles were on the stretch, but had suffered no injury. The cellular substance covering their tendons was deeply ecchymosed, so as to mark their course most distinctly. On replacing the head of the bone, the opening in the capsular ligament, through which it had escaped from its socket, could be distinctly seen. It was formed by a separation of the ligament from the interior side of the brim of the glenoid cavity from top to bottom; it was bounded at the top by the tendon of the supra spinatus, and at the bottom by the inferior edge of the tendon of the subscapularis. The rent was continued as far as the root of the lesser tubercle of the os humeri, and was of sufficient extent, but no more, to permit the head of the bone to pass easily through it; the inferior part of the capsular ligament, however (the part corresponding with the axilla), was perfect.

The great blood-vessels and nerves lay to the sternal side of the head of the humerus, and were forced a little out of their course. The axis of the head of the bone, in its dislocated position, was scarcely a quarter of an inch higher than the axis of the glenoid cavity.

FIG. 2.

I shall now, with a view of connecting the pathology with the practice, briefly advert to the practical inferences which may be drawn from the facts which the anatomy discloses.

Those inferences, it will at once be seen, are, with one or two important exceptions, in accordance with the practice of the most experienced surgeons, ancient as well as modern: they have, therefore, but slight pretensions to originality, but they are not, perhaps, on that account the less worthy of attention. It is always of great importance

to be able to add the sanction of reason to the conclusions of experience; without this sanction, the best rules of practice are liable to a misapplication, which may put them on a par with the worst; besides, rules of practice which rest *merely* on what is called *experience*, can have but slight claims to our confidence, when we remember that the *experience* of one age, or of one country, is usually found in opposition to that of another.

I. It would appear that the resistance to the reduction of a recently dislocated shoulder proceeds altogether from the

spasmodic contraction of the irritated muscles about the joint, and not from "the neck of the bone being tightly embraced by the ruptured capsular ligament." The latter opinion, though supported by some of the highest authorities in surgery, cannot be maintained against the evidence of pathology; the painful and dangerous practice of violently twisting the joint, "in order to enlarge the rent in the capsular ligament," should therefore be abandoned. If muscular contraction be the only, or at least the chief obstacle to be overcome, it would follow, that, previously to applying extension, we should have recourse to such means as have a tendency to diminish the tone of the muscular system generally, and to exhaust the irritability or power of contraction in the muscles of the affected limb in particular. To effect the first object, we may employ general bleeding, the warm-bath, and nauseating doses of tartarized antimony; and for the second, nothing is so effectual as gentle, but *long-continued* extension. But there is a property connected with muscular power, of which we may often avail ourselves with great advantage, even previously to having recourse to means which are calculated to act *directly* in diminishing the force of muscular contraction. It has been justly observed by John Hunter, that "muscles may be taken by surprise," and their force in this way eluded, rather than overcome; he asserts, that before a muscle can put forth its full force, it must be in a state of preparation for action, and this state of preparation must be produced either by the stimulus of the will, conveyed to the muscle along the nerves, or by a mechanical or chemical stimulus acting directly on the muscle itself. He accounted in this way for the great resistance which a joint opposes to an external force tending to produce dislocation, when it is *prepared* to meet it, as compared to that which it opposes to a force which takes it *unaware*. A man, for example, may leap from a height of twenty or thirty feet, and land on the hard ground, without producing dislocation of the ankle; yet he may suffer this injury by merely slipping *unexpectedly* from a height of one foot, as when (miscalculating the number of steps in a flight of stairs) he steps down one more than he reckoned

on. This law of muscular action is now universally acknowledged, and may be applied with advantage in the reduction of dislocations.

If before assistants are called in, or any apparatus is applied, the surgeon (while he appears to be occupied merely in ascertaining the nature of the injury) applies a gentle extension at the wrist, and, slowly raising the arm to nearly a horizontal position, suddenly pulls it upwards and a little forwards—that is, towards the patient's face—while, at the same time, he suddenly pushes the trunk backwards by pressing, with the left hand, below the axilla, he will, in a great number of *recent cases*, succeed by this simple process in reducing the dislocation. His success, however, will in a great measure depend on the *unexpectedness* of the attempt; he should therefore endeavour to divert the patient's attention from his proceedings; and I know of no means so effectual for this purpose as inducing him to describe circumstantially every thing connected with the occurrence of the accident. This is a theme on which all patients, who are at all able to express themselves, are sure to expatiate with the greatest satisfaction, and once engaged on so engrossing a topic, it will require but a small degree of tact on the part of the surgeon to seize the favourable moment when he can apply his force with the greatest advantage.

II. It would seem that in *luxation into the axilla*, muscular contraction operates in opposing reduction by pressing the head of the humerus (particularly that part of it in which there is a fossa separating the proper articular surface from the greater tubercle) against the inferior part of the brim of the glenoid cavity; and it would appear, from a case described by Sir Astley Cooper, that the muscle which is chiefly, if not exclusively, concerned in causing this pressure is the supra-spinatus: the obvious practical inference is to relax this muscle, as well as the deltoid, by raising the arm to nearly a right angle with the body, previously to applying any extending force, and above all things, not to use *any* force in pressing the head of the bone *upwards*, for so long as it lies on the *cervix* of the scapula, the pressure upwards only tends to lock it more firmly with that bone; and when

it is once clear of the brim of the glenoid cavity, it will start into the socket by the mere traction of the muscles.

III. With respect to the *direction* in which the extension is made, for the reduction of dislocation into the axilla, the practice of experienced surgeons, in all countries, seems now to be nearly uniform. The arm is usually raised to nearly a right angle with the body, and while a gentle extension is made by pulling at the wrist, the arm, used as a lever, is moved upwards and downwards, and to each side, so as alternately to relax all the muscles about the joint. It is true that in the method of reduction by the heel in the axilla, (which has the reputation of being a very successful one,) the arm is drawn downwards in a direction nearly parallel with the body; but it by no means follows, because this method is often successful, that the force which is employed is most advantageously applied: the desideratum is to effect reduction with the least possible degree of violence to the parts, and if it were ascertained by comparative experiments, conducted on a large scale, that two methods of reduction were equally successful, but that the object was effected in one by the employment of half the force which was employed on the other, it is manifest to which the preference should be given. And again, if it be true that in some cases the supra-spinatus muscle, retaining its connexion with the greater tubercle, is the cause of the resistance to the extending power, it is obvious that this resistance can be best overcome by raising the arm, and thus relaxing the opposing muscle. The success which not unfrequently attends the method of reduction (first recommended by White, of Manchester) by drawing the arm directly *upwards*, in a line parallel to the axis of the trunk, is no doubt to be attributed chiefly to the relaxation which it effects on the supra-spinatus and deltoid muscles: it is probable, also, that in this position of the humerus, the head of the bone is in some measure unlocked from the neck of the scapula, against which it is (when dislocated downwards) strongly compressed by the contraction of the muscles. Several years ago, the method of White was frequently resorted to in this country, for the reduction of old dislocations of the humerus—as the large ring in the cross beam of the anti-room

in Steevens' Hospital testifies; the method, however, has of late years fallen into disuse, a proof that it has no great advantage over the means now generally employed. The British surgeon will be a little surprised to find this method introduced as “a new and important mode of reduction,” in the *Hôtel Dieu*. M. Malgaigne, the gentleman who introduced the practice to the notice of M. Dupuytren, stated, in his address to the class, that the anatomy and pathology of this kind of dislocation had led him to adopt the method before he was acquainted with *the method of Mothe*. The method of Mothe, as stated by M. Malgaigne, “consists in making extension, the arm being lifted up forcibly, and consequently shortened, instead of extending the limb in a depressed and elongated position.” M. Mothe's Memoir, in which he lays claim to the *invention* of this new method of reduction, was presented to the Academy of Surgery in 1785. Mr. White's paper, in which he particularly describes the same mode of reduction, was printed in 1764.

IV. In Dublin, as in Paris, and in Berlin, and in Germany generally, we apply our extending power to the fore-arm, in preference to the arm; the application is far less painful, as any person can ascertain by applying alternately strong pressure to his own fore-arm at the wrist, and to the arm above the condyles of the humerus*; besides, we think that the pressure above the elbow causes the biceps and triceps muscles to contract more forcibly; and, lastly, when the extension is made at the wrist, the surgeon has more power in directing the motions of the limb.

V. Great stress is laid, by most surgeons, on the advantage of fixing the scapula, as it is called; it may be doubted, however, whether the thing be possible, or, if possible, advantageous. It is quite plain that a split cloth, or a napkin with a hole, through which the arm is passed, can, when the arm is strongly extended, act only on the inferior costa of the scapula, or rather on the walls of the axilla formed by the edges of the latissimus dorsi, teres major, and pectoralis major muscles. The whole effect

* There is scarcely a part of the body so intolerant of pressure as the inside of the arm, immediately above the condyles: this is no doubt owing to the superficial situation of the ulnar nerve, and its proximity to the bone at that spot.

of this force can be no other than to push the inferior angle of the scapula backwards and upwards, consequently to direct the superior angle and the glenoid cavity downwards, and, by acting on the pectoralis major and latissimus dorsi, to draw the head of the humerus inwards towards the ribs—that is, to remove it *from* the glenoid cavity. To obviate this objection, some surgeons recommend pressure to be made by the hand of an assistant on the acromion of the scapula, so as to push it backwards, while the humerus is drawn downwards and outwards: but it is plain, that unless the force which the surgeon applies to the head of the scapula, to keep it back, be at least equal to the extending force which is applied to the arm, the scapula cannot be *fixed*—it *must* follow the arm. Besides, when the arm is raised, the deltoid fills up the sub-acromial space, and renders it impossible to apply any appreciable force to the acromion. As the neck of the scapula cannot be pushed *upwards*, it is proposed, by Bonn, to disengage the bones by pressing the head of the humerus *downwards*, at the moment when the extension is at the utmost: the proposal is a most rational one, and has been adopted for several years past in the County of Dublin Infirmary, as I think, with considerable advantage.

VI. When a greater power of extension is required than can conveniently be applied by the unassisted strength of men, I have for upwards of twenty years employed the mechanical power of the lever, in preference to the pulley. The lever has, in the first place, the advantage of being always at hand, as there are few places in which a pole or a ladder cannot be readily procured; but its superiority over the pulley consists in the facility with which the direction of the extending force can be varied, while the force is still maintained, and the suddenness with which the force can be withdrawn as soon as it has produced its effect. The manner in which I am accustomed to employ the ladder, as a lever, will be best understood by a reference to the subjoined sketch.

VII. The anatomy of the recent case of dislocation *forwards*, settles the long-disputed question as to whether or not the humerus can be dislocated *primitively* in any other direction than *downwards*, or into the axilla. It is

quite plain that, in the case of Wilson, the head of the bone was thrown at once forwards into the situation in which it appears under the clavicle, as the inferior portion of the capsular ligament was not ruptured, and the attachment of the subscapularis and teres minor muscles, to the inferior costa of scapula, remained undisturbed. Perhaps there is not, in the whole compass of surgical pathology, any point, the determination of which is of more importance, in a practical point of view, than this. For if (acting on the opinion so generally entertained, that, in dislocation forwards, the head of the humerus *first* escapes into the axilla) we endeavour to draw the humerus downwards, it is obvious that the attempt must be attended with the most extensive injury to the subscapularis muscle; in fact, the muscle must either be torn right across, or separated from its attachments to the scapula or to the humerus.

The objection to drawing the head of the bone *downwards* into the axilla, for the reduction of dislocation *forwards*, of course applies exclusively to the primitive dislocation in that direction. In such a case, the clear indication is to force the head of the bone *backwards* towards the glenoid cavity, the axis of which is, as nearly as possible, in a line with that of the head of the humerus: this can be effectually done by applying a fulcrum immediately below the axilla, and using the dislocated arm as a lever of the first kind; the surgeon should therefore place his left arm, extended horizontally, immediately below the walls of the axilla, between the dislocated arm and the chest, and then, grasping the wrist in his right hand, he should draw the arm forcibly across the patient's body.

CASE.—The Hon. Col. Gore, of Dublin Castle, aged about 56, a healthy and vigorous man, was overturned in his carriage on a very dark night, the carriage falling sideways from a causeway, which was raised six or eight feet above the level of the adjoining field. When the side of the carriage struck the ground, he was conscious of having received a severe shock on the elbow, which rendered the arm powerless; he sustained no other injury. I saw the Colonel in less than an hour after his accident, and found that he had suffered a dislocation of the left humerus forwards. Standing before

him, I placed my left arm, extended horizontally, under his axilla, and grasping the wrist in my right hand, I drew his arm rapidly across his body, so

as to bring the hand in contact with the right hip; the bone snapped into the socket at the first effort.

FIG. 3.

Explanation of the Engravings.

FIG. 1.

- A, Deltoid.
- B, Scapula.
- C, Head of the humerus.
- D, Shaft of the humerus. The biceps and coraco-brachialis before, and the triceps behind the bone.
- E, Subscapularis.
- F, Teres major.
- G, Latissimus dorsi.
- H, Pectoralis major.
- I, Coracoid process.
- K, Edge of the torn capsular ligament.
- L, Some fibres of the subscapularis embracing the neck of the bone.

FIG. 2.

- A, Internal face of the scapula.
- B, Neck of the scapula.
- C, Coracoid process.
- D, Depression between the head of the os humeri and the greater tubercle.
- E F, The line of direction of a force acting on the head of the dislocated bone, before it has been disengaged from the neck of the scapula.

FIG. 3.

The manner of employing the ladder for the reduction of a dislocated shoulder.

A, the foot of an assistant placed on the lower end of the ladder, to prevent its rising when the upper end is pressed down.

B, a folded sheet, or table-cloth, for the counter-extension; the ends may be made fast to a ring, or other fixture in the wall, or may be held by two or three assistants standing on a table.

C, the hands of the assistant, who slowly depresses the lever, until the surgeon, who

stands at D (astride of the ladder), announces that the bone has returned to its socket. While the extension is in progress, the surgeon from time to time presses the upper part of the humerus downwards, to disengage it from the brim of the glenoid cavity; once disengaged, it springs upwards into the socket, without the assistance of pressure from below. The surgeon, by standing astride over the ladder, has it in his power, by the pressure of his knee on either side, to give a lateral motion to the lever, while the extending force is still in operation. In dislocation forwards, the surgeon should press his left knee against the side of the ladder; this motion, by bringing the hand forwards, will throw the head of the humerus backwards.

A PIN EXTRACTED FROM THE URETHRA,

by the Tour de Maître; with Remarks,

By M. VIDAL DE CASSIS,

Of the Central Bureau of Admission to the Civil Hospitals of Paris.

A BOY, six years of age, was brought to me at the Bureau, a few days since. He complained of sharp and severe pains in the neighbourhood of the perineum. His parents told me that he had shortly before thrust a large pin into the urethra, with the head foremost. I examined the parts; the urethra was very narrow, and the passage tinged with blood. Upon pressing with the forefinger along the track of

the passage, the pains were greatly increased when I came within an inch of the anus; there the child said he was pricked.

I had no instruments lying by me, except a small dissecting forceps and some silver sounds. The forceps it was vain to attempt to introduce, and I was about to send the patient to the Hôtel Dieu, when the mother besought me to do something for the immediate relief of her child. I then conceived a very feeble hope of the possibility of catching the point of the pin in the eye of a sound, and of extracting it in that manner. I introduced a small curved catheter, with its convexity upwards; and when its extremity reached the bulb, the child cried aloud with pain; upon which I applied the *tour de maitre*; but instead of pushing the instrument forward into the bladder, I drew it back briskly; when, to my great astonishment, I found the pin engaged in the lower eye of the sound. Nothing, I honestly confess, was farther from my expectations than this fortunate issue; for though it was reasonable to make a trial of catheterism, there was no calculating upon the circumstance which led to the result. I should observe, that at the Bureau we employ cerate for lubricating the sounds, and, in the present instance, the cerate in the eye of the instrument was rather hard, which no doubt contributed essentially to the success.

To the speculative I leave it to draw what inferences they please from the preceding fact; for my part, I must say that necessity alone would tempt me to repeat the operation, so persuaded am I that chance had the chief merit in the performance. Examples of the introduction of foreign bodies into the urethra are by no means rare. Morgagni mentions several cases in which wanton girls had slipped pieces of bone combs into the passage. In the Leipzig Acts there is the case of a young woman who passed a large needle into the bladder, and assured her attendants that it had come there by swallowing. A girl of Parma, in the way of frolic, had a large needle, with an ivory head, put into her urethra by one of her female friends who lay with her; it passed into the bladder, and had to be extracted by an incision through the vagina.

It is to be observed, that most of the

cases of this description on record are those of females, and in all the foreign body generally passed into the bladder. But in the following history, which is related by Lamotte, a striking resemblance to the case given above will be perceived. It is extracted from his *Complete Treatise on Surgery*, vol. ii. p. 376.

"In the month of June, 1692, an unmarried woman, of religious habits, came to me, and told me that a large-sized pin which she used for her napkin had slipped into her bladder, and gave her great pain. As the accident, according to her own story, happened in the course of the preceding night, I merely observed to her that I thought it impossible; for I did not wish to add unnecessary pain of mind to the bodily grievance which she already suffered. She shewed me a pin of the same size as that which had entered the bladder; it was of the largest description. Though I had no hope of speedily rendering her any assistance, I introduced the sound three several times, with all the care and patience I could command. I touched and felt the pin very readily, but each time I was obliged to leave it behind when I withdrew the instrument. On sounding, however, for the fourth time, I perceived that by a lucky chance I had entangled the pin in the eyes of the catheter. I immediately introduced the middle finger of my right hand into the vagina, and with this I supported the pin, whilst with the left hand I drew it out along with the sound. The manœuvre was perfectly successful, but it cost the patient much pain, for the point which projected from the instrument lacerated the passage in its exit. The sore, however, soon got well, and the woman had not to keep her bed an hour. Lithotomists may smile at my alarm about extracting a pin from the bladder, since at the worst an operation would easily remove it, if nature herself had not provided a remedy. But such an operation, it should be recollected, would require the introduction of a forceps between two *gorgerets* or conductors; and after all, the pin might be seized crossways. In the present case I will leave it to be conceived how much mischief might be occasioned by such an accident, considering the length and thickness of the pin*."

* From the *Journal Universel et Hebdom.*

COMPLICATED CASE OF CARBUNCLE.

To the Editor of the Medical Gazette.

SIR,

If you think the enclosed case worth recording in your valuable journal, I shall feel obliged by your inserting it in an early number.

I am, sir,

Your obedient servant,

HENRY EWEN,

Member of the Royal College of Surgeons.

Long Sutton, Lincolnshire,
May 14, 1833.

May 3, 1833, I visited Mr. George G. æt. 37, who, when I saw him, did not consider himself at all seriously ill, although in bed, having a severe boil, as he called it, on his left buttock. On examination, this boil appeared decidedly carbuncular; the apex of the conical tumor had several small openings, presenting a sieve-like appearance; into this I made a free crucial incision. His general health had not been good for some weeks past, but his appetite had not been impaired until the day preceding my visit. The tumor first commenced ten days since, accompanied with chills and heats, and lassitude. Six days ago he rode on horseback thirty miles, which he says did him great harm; his tongue is rather furred, and he has some fever; pulse 34; bowels rather constipated.

Foment. Papav. Cataplasma fermenti.

R Sulph. Mag. ʒij. Carbon. ʒij. Aquæ Menth. Pip. gr. ʒiiss. M. f. haust. 3tis horis sumend. donec alvus responderit.

4th, 9 A.M.—Has had a restless night; tongue furred; skin hot; face rather flushed; pulse more frequent. The medicine has operated three times; the stools very dark coloured, and highly offensive; the carbuncle appears going on well.

Apply the Nitric Acid lotion with the poultice. Sumat Haust. Salin. in statu effervescenti, 3tis horis.

4 P.M.—Sent for urgently, and found him very anxious, and complaining of great uneasiness about the præcordia, with difficulty of breathing, and feeling of faintness; his face was flushed; skin hot; and pulse 96, but without much hardness. As he was urgent for

me to bleed him, having, as he said, experienced very similar sensations about six years ago, when bleeding gave great relief, and thinking there might be congestion about his lungs, liver, and other internal organs, I took away about 14 ounces of blood, and with great relief to his symptoms: the blood was neither cupped nor buffy.

Sumat vespere Liq. Opii Sedativ.

℞xxxv. and the following pills:—

℞ Calomel. ppi. gr. v. Pil. Rhei. Comp. gr. x. M. f. Pilul. iij.

5th, 8 A.M.—Passed the night comfortably till 4 o'clock this morning, when he became very restless, and experienced the same sense of fainting as yesterday; he complained that "the draught had not sent him to Elysium;" pulse 108, and easily compressible; tongue dry down the centre, with a yellowish fur, white and moist along its edges; has passed no urine during the night; no further evacuations from the bowels since last evening; had bilious vomiting whilst I was with him.

℞ Calomel. gr. j. Pulv. Opii. gr. ss. Camphor. gr. iij. in Pil. 3tis horis sumend. et haustus aper. ut antea donec alvus respond.

12 P.M.—Considerably relieved by the pills, and expresses himself as much more comfortable.

4 P.M.—Skin very hot; tongue drier; sighing; the slough is rather dry, and has no disposition to separate.

Baln. tepid, 100° F.

He fainted on coming out of the bath; in a short time after he passed a very copious dark-green and offensive motion, and expressed himself much relieved.

Continue the Calomel and Opium, and Camphor, and take with each dose, Haust. Salin. in statu eff. c. Sulph. Quinina, gr. j. Wine and water, and beef-tea, allowed.

6th, 9 A.M.—Has passed a comfortable night, and expresses himself as feeling much better; pulse 112, easily compressible; tongue less dry; has passed about three pints of urine, which has a very dark grumous looking deposit; the carbuncle presents the same appearance as yesterday; the slough has no disposition to separate.

Vespere.—Rather delirious; skin hotter; tongue parched and dry; pulse 120.

Apply the Spirituous Lotion to the head.

7th, 4 A.M.—Was called to visit him, and found him violently delirious, refusing his medicine and wine; pulse 120; placed him in a tepid bath, at 98° F. for a few minutes; ordered his head to be shaved, and a stream of cold water to be poured from a height upon it. Mr. —, possessing considerable moral influence over him, prevailed on him to take his medicine and some wine. At 10 A.M. found him quiet and rational; pulse 120; tongue brown and dry. At 4 P.M. has remained free from delirium; bowels have acted twice; the stools are more bilious.

R Ext. Opii, gr. iij. Calomel Ppi. gr. iij. s. s. et omni horâ dum nigrat, gr. j. Ext. Opii, et gr. ss. Calomel Ppi. Wine and water liberally allowed.

About 8 o'clock in the evening he jumped suddenly out of bed, and had a strong convulsive paroxysm; afterwards, when he had taken gr. v. Ext. Opii, he had three hours good sleep.

8th, at 4 A.M. was called to him; pulse 140; skin hot; tongue dry, with a black fur at the back of it; countenance more sunk; pupils contracted, with a dropping of the upper eyelids; delirium; concentration of heat about the hands, which felt burning hot; abdomen distended, and the bladder in particular. A catheter was introduced, and about three pints of dark-coloured urine drawn off. During the day his vital powers progressively failed; and it was only by a great apparent effort he could maintain his consciousness for a few seconds at a time. In the afternoon his delirium became more violent, and he expired between 8 and 9 in the evening.

May 9th.—*Inspectio Cadaveris, twenty-two hours after death.*—The brain was a very fine one, large, and perfectly healthy. The lungs were more engorged than usual, and of rather a darker colour than natural; the heart was flabby, paler than natural, and its muscular tissue softened, but the external and internal membrane and valves were not diseased. The alimentary canal was healthy, with the exception of gaseous distention, and the small intestine contained a viscid greenish matter. The liver was healthy, but paler than natural, and contained less blood than is usual. The spleen was softened, and disorganized; the pancreas healthy; the kidneys were softened, and their natural structure broken up and disor-

ganized, but in a less degree than the spleen. The bladder was contracted, and its lining membrane blanched. The carbuncle was flabby, and the fibres of the gluteus muscle beneath pale and softened.

REMARKS.—The above-detailed case possesses some points of pathological interest, more especially if viewed in connexion with some valuable and interesting observations of Dr. Wilson, "On Fits and sudden Death, in connexion with Disease of the Kidneys;" of which an account is given in the number of the Gazette for 9th of last March. The partial suppression of urine noticed on the 5th, and its extremely vitiated appearance subsequently; the suddenness with which delirium supervened, and its violent character; tended to excite a strong suspicion of some serious lesion of the kidneys. The likelihood of this idea was fully confirmed on dissection. It is right I should state, that in the treatment I had the advantage of Dr. Heald's and Mr. T. Caumack's valuable assistance.

INFLUENZA—SULPHATE OF QUININE AS A REMEDY.

To the Editor of the Medical Gazette.

SIR,

I BEG leave to forward this paper to you, with the hope you will insert it in your Gazette as early as convenient. As a constant reader, I subscribe myself,

Your obedient servant,

WM. RAWLINS, M.D.

Lincoln.

The prevailing epidemic, which by many has been so lightly treated, has proved a most formidable disease; and if dependence may be placed in the records of the bills of mortality, it has enormously increased the number of deaths in the metropolis.

In the city of Lincoln few families have escaped its influence, although at present not many deaths have occurred. The influenza does not indeed *immediately* cause the death of a tithe of its victims; but the shock which the aged and debilitated, and such as already possess a predisposition to pulmonary affections, receive, lays the foundation

of chronic diseases which will ultimately destroy life, though the sufferers may possibly survive the disorder itself.

As, by mitigating the primary symptoms, the sequelæ may be rendered less dreadful, I feel great pleasure in communicating to the profession, through your useful publication, the value of the sulphate of quinine as a remedy. The violent headache, sweating, pains of the loins and limbs, as well as the disturbed state of the circulation, are relieved at once by the exhibition of the quinine. The sooner medical treatment is had recourse to, after the appearance of the disorder, the better. The plan I have adopted is to give one grain of the sulphate of quinine every three hours, in the form of pill, together with \mathfrak{ssj} . of the following mixture:—

R Lac. Ammoniaci, \mathfrak{ssvj} .; Oxy mel Scillæ, \mathfrak{ssij} .; Coch. ij. mag. 4ta hora sumend.

At bed-time, \mathfrak{ssj} . vel \mathfrak{ssij} . of the trā. camphoræ comp., or from grs. v. to grs. x. of the pulvis Doveri, depending upon the state of the cough, expectoration, and the skin; at the same time the bowels to be kept *moderately open* with small doses of the compound extract of colocynth. I have tried other modes of managing the disease, but as far as my experience carries me, I should give the above the most decided preference. Bleeding I consider as inadmissible, and unless called for by some other symptoms not belonging to the epidemic, highly dangerous. By the *early use* of the quinine the cough will not acquire the same degree of violence; the constitution will at the same time be supported, and the better enabled to throw it off. It must be remembered that the epidemic cough is one "*sui generis*," depending upon different causes for its formation, to a common cough from cold.

The influenza is received, or more properly inhaled, through the lungs; the blood is soon contaminated, the heart over-stimulated, and the whole animal machine greatly excited, so that it is not to be wondered at that there should be such severe headache, cough, and perspirations. Common colds and coughs are generally most severely felt by the robust and pléthoric; not so with the influenza—the weak and phlegmatic suffer most from it; and those symptoms which have at first sight all the appear-

ance of being inflammatory, are not really so, but arise from the mass of blood being tainted: hence the violent action of the heart, and the great disturbance of the nervous system.

Lincoln, May 13, 1833.

APPEAL TO THE PROFESSION
RESPECTING THE
PROPOSED ALTERATION IN THE
APOTHECARIES' ACT.

To the Editor of the Medical Gazette.

SIR,

I AM glad to observe that you have placed the proposed alteration in the Apothecaries' Act in a correct point of view. That Act, with all its defects, has done much to improve the education of medical practitioners; and now an alteration is proposed, by which it will be virtually abolished. As you have explained, the Apothecaries' Company would cease to prosecute when obliged to prove that the defendant was not a member of any of the Scotch Colleges. To call it *an alteration*, therefore, in the Apothecaries' Act, is mere mockery. The Act might as well be repealed altogether, and much better in fact. This would be meeting the question fairly, for I do again repeat that the alteration proposed is equivalent to abolishing it.

I cannot help feeling some surprise at the apathy with which medical men surrender their professional privileges. Unfortunately there are many persons in this country who earn their subsistence by slander. There are some of these individuals in the profession—men who have not succeeded in private practice, and who live by ridiculing and abusing their more fortunate brethren. Medical men read bitter attacks upon the College of Surgeons and Apothecaries' Company; and although containing the grossest falsehoods, they are credited by many, for want of better information. The ridicule and buffoonery with which these attacks are frequently seasoned, create a laugh, and assist in bringing these useful institutions into contempt. When the bulk of the profession have been imposed upon by these calumnies, they naturally regard the

College and Hall with hatred and aversion. And when a plan is proposed for altering or abolishing them, they regard it with indifference, and most erroneously imagine that their own interests are not involved in the question.

If the proposed alteration in the Apothecaries' Act should be carried into effect, what will be the consequence? The Apothecaries' Company no longer having the power to prevent ignorant men from practising as apothecaries, the country will be inundated by empirics and unqualified practitioners. This will, of course, seriously injure the present race of medical men. Competition will reduce their charges, and a profession which is already too full will become still more overstocked. To a general practitioner I would say, "if you are rising in your profession, oppose to the uttermost a measure by which your future prospects may be blasted. If you are struggling with difficulties, and scarcely able to procure a precarious subsistence, you are still more imperatively called upon to oppose a measure by which your ruin may be rendered complete." To metropolitan lecturers, hospital surgeons, and physicians, I would say, "resist this measure for your own sake, even if you care nothing for general practitioners. Resist it, for if it passes you must submit to a mortifying diminution of your income. Pupils will not come in great numbers to London when they can commence practice without putting themselves to so great an expense. Recollect that it is only since 1815 that there has been so great a flow of pupils to London; for in 1815 the Apothecaries' Act came into operation."

As licentiates of the Apothecaries' Company are not allowed to practise in Scotland, I am at a loss to understand by what right members of the Scotch Universities can claim the privilege of practising in England? Really we must be a set of blockheads if we surrender our privileges so injudiciously to those who will not grant us any similar favour in return. Dearly shall we repent our folly when it is too late. And as our interests are so deeply concerned in this question, a public meeting of the profession ought to be called, to devise means to prevent the progress of the measure. I have merely pointed out the injury to medical men with which we are threatened. But the public at large

are equally interested in preventing the influx into the profession of a tribe of irregular practitioners, whom we ought to regard in the same light as a swarm of locusts. If you insert this communication, I will probably write to you again upon this and some other subjects, at a future time.—I remain, sir,

Your most obedient humble servant.

MEDICO-CHIRURGICUS.

May 16, 1833.

IMPERFECTIONS IN THE ACT OF 1815.

To the Editor of the Medical Gazette.

May 14, 1833.

SIR,

Your leading article, at page 182, has suggested the following observations, which are offered to you in the full assurance of your giving them a candid consideration, and a place in your journal, if they deserve it.

You have given it as your decided opinion, that the good effected by the Apothecaries' Company, under the Act of 1815, has much outweighed the evil. Granted: but is the evil, therefore, to remain? Let it be allowed that the Society has exercised its powers in the mildest and most liberal spirit possible; still, if those powers are such as cannot be wielded without inflicting injury—without doing injustice—they ought to be modified, or abolished. Lambro, the pirate, was

"The mildest manner'd man
That ever scuttled ship, or cut a throat,"

but this exception (however amiable) to the general rule, is no argument in favour of piracy.

The objections to the Apothecaries' Act are, in the first place, that it prevents many from practising, whose competency has been ascertained by well-constituted and lawful authorities. I allude not here to the members of the London College of Surgeons; because, however well they may have informed themselves upon *medical* subjects, their diploma was granted them without any examination but on *surgery*, and the accessory arts which minister to that *one* branch of the profession.

Secondly, the Bill is objectionable, because it is not calculated to protect the public against unlicensed and uneducated empirics, who may, any of

them, by the shallowest contrivances, and on the most frivolous pretexts, exempt themselves from all penalties with which the statute threatens them. From this, the most dangerous class of impostors with which society is infested, the counter-practising druggist is but a little way removed. He, certainly, in any new Bill to be framed, ought either to find his qualification or his punishment.

One thing, sir, you say, is clear: that if general practice in England be thrown open to the members of Scotch Colleges, it will place all the practitioners now settled here in a precarious and unpleasant position; both from its admitting Scotch competitors and from its annihilating the present protection against quacks. This is, at least, the substance of your assertion.

Now, as to fair competition—and we have no right to apprehend any other kind of rivalry, seeing that both parties in the contest will be members, legally constituted, of a liberal and scientific profession—one can hardly doubt that it will tend strongly to the advancement of medical science, to the individual improvement of practitioners, and to the ultimate advantage of the public.

With respect to the putting down of St. John Long and his tribe, that could be done, perhaps, as efficiently by his Majesty's Attorney General as by the Worshipful Company of Apothecaries; and it might be done upon the principle that any remedy, internal or external, directed and administered for gain, in the treatment of an internal or "medical" disease, shall be deemed the act of an apothecary, and punishable accordingly, when performed without due licence.

I repeat my acknowledgment that the Apothecaries' Company have used their authority, and interpreted their Act, most liberally; and so far from wishing to turn them out of office, I would rather see their jurisdiction in many ways extended. The surgeons, cowed by the superciliousness of Sir Robert Peel, have shunk from their duty as the natural protectors of the public against blacksmith-dentists and bone-setters. Let the apothecaries take up the abandoned cudgel, and lay it upon these (last-mentioned) rascals, as they deserve.

Finding my patience as completely

at an end as my paper, I must spare you the infliction of another sheetful. Let me end this, however, by assuring you of the undiminished respect of

Your reader,

Φ.

SUGGESTED IMPROVEMENTS OF THE APOTHECARIES' ACT.

To the Editor of the Medical Gazette.

SIR,

It is clear to me, from the general tenor of the memorial of the Society of Apothecaries, published in your last number, that no improvements in the Act of 1815 can reasonably be expected to originate from that body. No mention is there made of any defects in the Act—no suggestions are thrown out that its workings are attended with any practical inconveniences. On the contrary, the Society stand prepared to shew, first, that "all the benefits which the Act of Parliament was *intended* to afford to the public, have been fully attained;" and, secondly, "that the Act has been by them *properly and efficiently* administered." It certainly is strange, and to me quite unaccountable, that this memorial, drawn up with such apparent candour, should make no allusion whatever to the bill which passed in 1825, for the purpose of remedying certain real, or supposed, defects in the Act of 1815, and which for twelve months was the law of the land. That amended bill of 1825 was either unwisely brought in, or unwisely suffered to expire. It was either a good bill or a bad bill; and as it bore directly on the question at issue between the Scotch Colleges and the English Company of Apothecaries, it surely became the latter, who acted under its provisions for one year out of the eighteen, to state their opinions concerning it one way or another. No one, reading that memorial, could for a moment imagine that the Act of 1815 was in 1825 considered by the three estates of the realm as so defective as not only to call for, but actually to obtain, legislative interference.

Throughout the whole of the Apothecaries' memorial, there is, in fact, an indisposition to meet the several questions that arise fairly. Thus the limitation of general practice in England to those

licensed by the Apothecaries' Company of London, is defended, not as being a thing in itself good and desirable, but because something a great deal more absurd exists in Scotland, just as if two blacks made a white. So, when the Scotch Colleges contend that the act of 1815 is pregnant with injustice, the Apothecaries' Company reply that the Act has been *efficiently* administered. This may be true, but it is no answer to the allegations of the Scotch. Whether it is true, whether the Apothecaries' Company, in their mode of carrying the Act into effect, have, or have not, exceeded their powers, is a matter well worthy of investigation, and I hope to discuss it in my next, but at present I wish to confine myself to the more important branch of the inquiry—whether the Act of 1815 is perfect in all its parts—whether circumstances have occurred, in the course of eighteen years, calculated to shew any injurious tendency in it—whether, in short, it is susceptible of improvement, not by the Apothecaries' Company, but by the authority of parliament.

The grand question of apprenticeships first meets us. The Apothecaries' Company tell us they did not propose that clause; leaving us to suppose that they *objected* to it. Finding it in the Act, however, they defend it. This is what the world calls blowing hot and cold with the same breath. If an apprenticeship for five years really possesses all the advantages which the Apothecaries' Company represent in their memorial, it was their duty to have recommended such a clause to the House of Lords in 1815. But here, again, I complain that the Apothecaries' Company blink the question which, so far as the public is concerned, is mainly at issue. Granting the benefits of the apprenticeship system in the fullest sense claimed by its admirers (and I most willingly concede them), is it necessary that this should be a *sine qua non* to examination? Will no degree of study, no opportunities of practice, no undisputed skill, compensate for the want of an indenture of apprenticeship, duly stamped? Is it essential that *every* man practising in England and Wales should have gone through that ordeal? Would the Apothecaries' Company object to a clause permitting them, in the exercise of a sound discretion, to forego the preliminary process of apprentice-

ship, in certain cases, to be by them determined on—as, for instance, where a very full course of general study has been gone through—where a young man's parents had died young, and the guardians been careless and improvident—where the youth had been born and bred in the colonies, &c. &c.? I am sure the Apothecaries' Company would hail such an addition to their Act with joy, and dispense such a privilege with prudence and great public benefit. Then comes the further question of the *time* during which such apprenticeships should last. The Act says five years. Is the Apothecaries' Company prepared to say that this period would not admit of limitation? Would not three years answer every purpose?—and, in point of fact, have not the Apothecaries' Company, on many occasions, been satisfied with apprenticeships which, though nominally for five years, had *really* been for three only? I ask not this, out of enmity to the guardians and executors of the Act of 1815; it redounds to their credit; but I ask it, to shew that the Act is susceptible of some useful alterations.

There is another clause of the Act which appears to me to require revision. As the law now stands, a student who has not answered his questions to the satisfaction of the Examiners, must be sent back for six months; he cannot be sent back for less, and he cannot be sent back for more. Within less than six months the Examiners cannot re-examine him; and when the six months are elapsed, the pupil may claim a re-examination, and the Court cannot refuse him. Whether his defects be great or small, in anatomy or in medical botany, in the reading of a prescription, or in the translation of Celsus, in physiology, or in the diagnosis and treatment of diseases, in the elements of chemistry, or in his knowledge of drugs, the punishment is the same. For six months he must return to his studies—no matter whether it be the six winter months, when the business of education is brisk, or the six summer months, when it flags,—in either and all cases the penalty is the same! Is this clause of the Act of 1815 not susceptible of improvement? 'Twere absurd to argue the question. The Court of Examiners know it well; and when pressed upon the subject reply, "The Act is the act of the Legislature, not ours. It is our

business to execute the Act as we have received it; and it ill becomes us to find fault with an Act which the legislature has entrusted to our care and superintendence."

Here I shall pause for the present. In my next (if you will permit me to encroach so far upon your columns) I will attack the lion in his den, and attempt to determine how far the Apothecaries' Company deserve the credit which they assume to themselves, of properly and efficiently administering the Act of 1815.

I am, sir,
Your very obedient servant,
MAXILLA INFERIOR.

London, May 18, 1833.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

Annales d'Hygiène publique et de Médecine légale. Avril 1833.

AMONG other interesting articles in the present number are the following, which we shall briefly condense. The first a case of poisoning, medico-legally investigated:—

Detection of Arsenic in Bread. By
M. ORFILA.

In the month of July last, X., a locksmith of the village of G., went to spend the day with his brother and sister-in-law, Moreau. There was some talk about certain new flour that had been received by the family, and X. expressed a wish to see it. It was shewn to him; he took up a handful of it, and, after holding and examining it for a few minutes, threw it back into the bin, observing that he thought it better than his own. Two days after, the flour was used in baking, and thirteen persons, including M. and Mad. Moreau and their son, ate of the bread. They were all seized with violent colic and frequent vomitings. The bread was suspected to be the source of the mischief; and on the 2d of August experiments were instituted by two practitioners of the village, with a view to detect the poison. A loaf weighing from thirteen to fourteen pounds was taken; it had been baked three or four days before. Its

taste, without being disagreeable, left in the mouth for some time after an acrid feeling of a peculiar kind, though there was nothing metallic about it. It was gritty under the teeth, and sandy matter was found in it. The result of the experiments was—1st, that no trace of *arsenic*, mercury, zinc, antimony, &c. could be found in the bread; 2d, that it contained atoms of copper and iron, as well as phosphates of lime and magnesia. Without, however, pronouncing decidedly that there was no poison in the bread, the experimenters tried the following method of approximating to the truth. About three ounces of the bread, with a little meat, was given to a healthy dog, at nine in the morning. In a quarter of an hour he vomited without much effort. The same trial was made at three in the afternoon, with the same result. The dog, however, seemed nothing the worse for it. On the third day after, he was given some common bread and meat, with a little alcoholic extract of the suspected substance. The same symptoms supervened. In consequence of the general result, the experimenters conceived that there was reason to suspect the presence of a vegetable poison in the bread, and requested the *procureur général* to call in further assistance. Two chemists from Paris were accordingly deputed to proceed further with the analysis: but they soon concluded that there was neither arsenic nor any other mineral poison in the bread; and as for vegetable poison, they seem to have been dissuaded from attempting any search of the kind, on account of the mouldy state of the substance to be examined.

It was not until the 22d of November that M. Orfila was commissioned to test the suspected bread; but he speedily obtained from it a *notable* quantity of arsenious acid; and upon the evidence thus supplied, the accused, X. (who, by the way, had some moral and circumstantial points also made out against him) was condemned to death.

M. Orfila then proceeds to relate succinctly the experiments by which he arrived at the important result, and to shew how it happened that the four experimenters previously engaged in the inquiry had failed in coming to the same conclusion.

Having cut the bread in pieces, he treated it with cold distilled water; shook it for some time, and then left it

to stand for twenty-four hours. He then filtered, and applied the liquid hydrosulphuric acid test. The filtered liquor became yellow, without any perceptible precipitate. Some drops of hydrochloric acid were now added, to throw down the sulphuret of arsenic which appeared to be formed, but this required some days to effect; and here, probably, was the cause of failure in the experiments previously instituted. "It cannot be too often impressed on analysts," says Orfila, "that when arsenious acid is mixed with gelatinous and albuminous and vegetable matter, it may be so engaged with it as to be very differently affected by re-agents from what it is when merely in watery solution." The precipitate of sulphuret of arsenic and organic matter just mentioned, having been decanted and washed repeatedly with distilled water, was finally treated with a very fine filter, and washed with very dilute water of ammonia, which it is known dissolves the sulphuret without affecting any other matters in the precipitate.

The ammoniacal solution was then put into a watch-glass, and a little carbonate of potass and charcoal added. Heat was applied, in order to decompose any little animal matter which might still chance to be present in the mixture. The watch-glass and all was then pulverized in a porcelain mortar, and the powder introduced into a fine test tube. A red heat was procured over a lamp, and the metal arsenic was speedily produced.

M. Orfila concludes with some practical hints relating to his processes. In the first place, he says we should never neglect to pulverize the watch-glass when we have to deal with very small quantities of suspected matter, for we may not be otherwise able to detach the whole of the sulphuret. And again, in heating the mixture in the watch-glass, we must take care not to apply too great a heat, lest the sulphuret be volatilized or decomposed by the potass, and the metal thus escape into the atmosphere in the form of vapours. Finally, in order to economize the arsenic in the test tube, he recommends that, upon introducing the powder, we should draw out the upper extremity of the tube over a lamp. The volatilized arsenic is to be collected in the slender part of the tube, farthest removed from the heat which is applied.

If the sublimed arsenic be too minute in quantity to be detached from the tube, or the interior of the latter appear only to be covered with a dark crust, the part containing the crust should be immediately put into the flame of the lamp; in a few seconds it will become brilliant. If we wish to obtain the arsenious acid from the metallic crust, the best method is—not to chace it up and down, as has been recommended, but to put it into a tube of moderate length, open at both ends, and apply heat to the part where the crust is: the oxydation will soon take place. As to the metal, it is recognized—1, by its physical properties; 2, by the garlicky fumes which it emits when thrown on burning coals; 3, by its property of being dissolved in nitric acid, with heat, leaving after evaporation a white residue, which on being dissolved in pure water, and treated with hydrosulphuric acid, yields in a few minutes a characteristic yellow precipitate—the sulphuret of arsenic, soluble in ammonia.

M. Tardif's case—Attempted Assassination.

We mentioned in this journal, a few months ago, the leading particulars of this case. M. Tardif, it will be remembered, is the magistrate on whose life an attempt was made by night in his bed-chamber—some say by his own hand; but M. Breschet, to whom the medico-legal investigation of the matter was committed, is clearly of opinion that there was actually an attempt at assassination. The arguments of this gentleman are given here at great length: we have only room for a passage in the summing up.

"An examination of all the circumstances attending this affair shews that M. Tardif was not the author of the wounds on himself—1, because from the situation and direction of the wounds, it should have been the left hand with which they were inflicted, whilst the left forearm of M. T. was evidently employed in parrying, and was wounded in the same manner as his body; 2, it is not reasonable to conclude that the right hand held the cutting instrument, for the wounds all came from the left side of the sufferer.

"My general inference is that there was here no suicide, attempt at suicide, or pretended attempt to commit that crime. M. Tardif was wounded by

her hands than his own. His *assassination* was attempted."

But one of the most prominent papers in the present number of the *Annales*, is the medico-legal inquiry into the

Affaire Ramus—Case of Poisoning and Murder.

The head of the murdered Ramus was found in the Seine, his legs in another part of the river, and his trunk in the sewer of one of the streets in Paris. The medical part of the inquiry relative to the appalling crime which led to this mutilation, was conducted by MM. Chevallier and Boys de Meury. An exceedingly minute detail is given by these gentlemen regarding the exterior of the body, in the first place. The head, trunk, and legs, having been put together, the length of the subject was measured: the age was calculated from the appearance, and put down at from 30 to 35. The features, it seems, indicated no violence previous to death. Certain moles, &c. together with the age, height, &c. ascertained the identity. The mode in which the amputation of the members was effected, is fully detailed, and it is observed that the incisions for the purpose were made very soon after death, and by a practised hand.

A most accurate autopsy was held on the remains on the 2d September, when the following conclusions were arrived at:—1. That Ramus did not die a natural death; that, in fact, he had not laboured under any disease, such as poplexy, aneurism, &c. terminating fatally. 2. That his death was from hæmorrhage, his throat having been cut. 3. That the mutilations of the limbs and trunk were effected soon after death. 4. That the deceased during the murderous act was nearly incapable of resistance, in a state of drunkenness or narcotism. 5. That his death occurred about three hours after food had been taken into the stomach. 6. That four days at least had elapsed since the murder. 7. That the mutilations were effected with a butcher's or a kitchen knife. 8. That it was impossible to say exactly how long the parts of the dead body were in the water.

The conclusions of M. Chevallier on the contents of the stomach and intestines were—1st, that the presence of alcohol and hydrocyanic acid among

them was ascertained; but 2d, that it could not be positively said that the spirituous or acid substance might not be the product of fermentation in the stomach during the six or seven days that had elapsed since death; and 3d, that there was no evidence of other poisonous matter present in the body.

It is an interesting and most important point that traces of hydrocyanic acid were thus detected in the contents of the stomach seven days after the poison was administered; for that it *was* administered, subsequent information put beyond a doubt. Three weeks after the medico-legal reports were given in, the murderer was ascertained; he was arrested on the 8th of October, having thrown himself in the way of the police by returning to Paris, when he heard that his son, who was an apprentice to an apothecary, had been taken into custody. He confessed his crime after some hesitation; and it came out that, before cutting his victim in pieces, he made him swallow a mixture of brandy and prussic acid. The criminal was tried in January last, on a capital charge of poisoning, murder, and robbery; he was found guilty and executed.

There are several other medico-legal, as well as hygienic, articles, in the present number, which we have no doubt would prove interesting to our readers; but we must defer our notice of them until another opportunity.

Graphic Illustrations of Abortion and the Diseases of Menstruation; &c. &c.

By A. B. GRANVILLE, M.D. F.R.S. F.L.S. F.G.S. F.R.S. &c. &c. 4to.

This is really a splendid volume, and one which in an especial manner deserves the patronage of the profession. The plates are beautifully executed; some of them superior, as specimens of art, to any thing which has hitherto appeared in this country. The work has been printed on the author's own account, and is sold at what cannot be a remunerating price, especially as the number of impressions is very limited. We decline entering at present on any notice of the text, because it is very brief, and because the author announces the immediate appearance of an octavo volume, in which his views are more fully discussed. As we have been under the necessity of differing much and frequently from Dr. Granville, it affords us plea-

sure on this occasion to speak in terms of unmingled commendation, and we shall give to his opinions, when they come before us, our best attention and most impartial consideration.

MEDICAL GAZETTE.

Saturday, May 25, 1833.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

THE GOWER-STREET VALETU- DINARIUM.

Our attention has been directed by a correspondent to a series of laudatory articles on the Gower-street School, which have appeared in the *Times* during the last month. It does, as he observes, seem rather extraordinary that so many specimens of the puff direct, collusive, and oblique, should have been thus suddenly indited, particularly when we consider the very unceremonious manner in which similar notices were last year rejected as “advertisements.” The explanation, however, is very simple, and consists in the fact that one individual, who has lately taken up the cause, is a friend of the editor, and a frequent contributor to the paper, being well-known as the author of certain articles on clerical matters. Now we have no doubt of the party in question—we mean the Editor—having been led to believe, that in giving admission to these paragraphs, he was supporting a laudable public object, instead of a private speculation. Such we believe to be the unravelling of the mystery which has perplexed our correspondent, and may possibly have somewhat puzzled others as to its immediate cause, although the thing has been too much overdone not to be attributed to private influence by all who happen to have noticed it—even if the gentleman alluded to had been less

communicative regarding his influence with —, *the Redacteur en chef*.

But this leads us to another instance in which the zeal of the partizan has greatly outrun his discretion. The clergyman who has taken so active a part, both directly and indirectly, on this occasion, and who officiated at the opening of the hospital, because Dr. Moore, the rector of the parish, was “indisposed,”—he, we say, in that solemn place where all hollow pretences are supposed to be laid aside, was injudicious enough to represent, as an act of disinterestedness and liberality on the part of the medical professors, the resignation of a large amount of pupils’ fees for hospital attendance. Now it is apparent to every man whose intellect is above the grade of imbecility, that, by the act in question, they resign nothing—sacrifice nothing—hazard nothing. There are at present no funds of any kind by which to support the hospital, supposing it built and furnished; but it is thought that a possibility—a chance, however slender, may exist, of getting it opened, by giving up the fees of the pupils, should any enter. The state of the argument, as regards the Professors, is this:—“It is quite impossible for us to make a beginning of this hospital, unless we agree to give up the fees; but we can get this represented as a very handsome and liberal thing on our part, and if it can be thus set a going, each of us will receive an additional fee from every pupil whom the hospital attracts, because he will also enter to our lectures.” Now this is all very fair reasoning, according to the ordinary rules of worldly wisdom; but when it is blazoned in the papers and journals of the day, as an instance of liberality—and, above all, when this calculation of chances is held up to a congregation in a place of worship, as emanating from motives which call for the commendation of a

christian minister,—it becomes offensive and disgusting,—it is repugnant to all good taste, and violates every notion of propriety and candour.

The truth is, that the Council of the London University are thought by the Professors to have spoken somewhat too plainly as to the real state of the institution; and as the latter gentlemen have now become, in a manner, the renters of the school, they are resolved not to fall into a similar mistake. Besides, they have not lost sight of the pithy question lately put to them in the *Lancet*: “do men of business who are desirous of making a push to improve their circumstances, represent themselves as insolvent?” The hint, it is clear, has not been thrown away.

At present the affair stands thus. The Council, finding that all the money originally subscribed has been expended, and a considerable and increasing debt accumulated, declare in their report, that in order to enable the institution to be carried on, “an increase in its funds, of not less than a thousand a-year, is *essential*.” The proprietors generally seem to have made up their minds pretty well to the result, and are evidently not at all disposed to come forward with this or any other sum; and the circumstance of the shares having fallen in the market from 100*l.* to 25*l.* shews pretty clearly the anticipations entertained of the future prosperity of the concern.

But the Professors, and especially those of the medical department, are very differently situated, because they derive an income from the establishment, as long as it can be kept together, whatever may become of the proprietary. Accordingly they are very naturally making a great effort to go on at all hazards, and in order to secure this for the present, have become bound for the expenses of the next year. But inasmuch as the number of pupils which has

hitherto been collected, supposing it to remain undiminished, is not sufficient to answer the purpose, they are resolved to adopt Wakley’s advice, and *make a push*:—in this push originates the hospital.

We stated our belief that this scheme would not be carried into effect; and as we were mistaken in this, inasmuch as the first stone has actually been laid, we hasten to put our readers in possession of the fact. We were induced to imagine that they who had not deemed 158,882*l.* 10*s.* too large a sum to be spent on lecture-rooms and façades, would esteem 4000*l.* somewhat scanty for the erection and endowment of an hospital; and had the matter rested with the Council, probably such had been the case, for in their report they speak of it merely as a speculation, and admit the great risk and difficulty attending it.

But it is evident that the Professors, for the reasons above alluded to, are very differently circumstanced: it is “*neck or nothing*” with them, and accordingly, despising all ordinary modes of calculation, they have already begun the hospital;—we have seen the foundation, and can vouch for it. Nay, lest there should exist any doubt as to the purpose of the building (for, from its dimensions, this is a very possible occurrence), a tablet has been engraved, on which it is expressly declared to be the *Valetudinarium* of the London University*.

* We have before noticed the rage which is abroad for striking names—such as Emporium for a broker’s shop, Lactarium for a dairy, Vestiarium for a tailor’s, Seminary for a ladies’ school, University for a young gentlemen’s, &c.; but we must confess we were not prepared for the novelty of styling the Gower-Street Hospital (that is to be) a *Valetudinarium*. Have we misunderstood the object of the proposed erection, or have the curators of the work committed a misnomer, in using a word of doubtful meaning to designate their hospital? In the only passage where Celsus uses it (*qui ampla valetudinaria nutriunt*,) it clearly implies a place in which slaves or cattle were kept in good condition for the market; and though it is found in one or two writers of the iron age of latinity, not one author of any note has ever used it for what we call an hospital. When a

Now it is quite clear that gentlemen renting a theatre, may, in the furtherance of their objects, build a "Valetudinarium," or any thing else, on their own responsibility, which they think likely to prove attractive; but when the public are called upon to contribute to it, as to a charitable purpose—when a certain portion of the press is systematically engaged in aiding the deception—when the pulpit itself is made use of in hyperbolical commendations, and in attributing liberality and disinterestedness to those whose benevolence consists in calculating what will bring them in the greatest amount of pounds, shillings, and pence—then it is time that the naked truth should be told; and in our pages, if in none other, shall it be recorded—that the North London Hospital is a job, and the alleged disinterestedness in giving up the pupils' fees, mere hypocrisy and humbug.

We say, then, that this same Valetudinarium is a private speculation, with which the interests of the public have nothing to do;—it is the offset of a school, in which the object of improving their finances is hid under the cloak of charity; and the real purpose of affording a lure to pupils, is to be accomplished under the pretext of relieving the poor. The hospital, too, is in a part of the town which does not require it, being in the immediate vicinity of the Middlesex; one already complete, yet all the wards of which can scarcely be kept open even now, so that we are told, by their advertisements, some of them must be closed, if any portion of the income be abstract-

ed. Nay, the new building is not even required for the pupils, inasmuch as the Middlesex Hospital is so near, that the Council of the University offered, under certain conditions, to consider it as connected with their school. An hospital may, indeed, be required in the northern part of the metropolis, towards Islington, but far from its present site; and it ought to be on a large scale,—not gauged by the regulations of the College of Surgeons and Society of Apothecaries. An undertaking not required to serve some private and temporary purpose is never hurried on in the indecent manner in which this has been, nor its ultimate success brought into desperate hazard, except to secure some object by its immediate though but nominal existence; for, be it remembered, that even the bare walls, diminutive as is their scale, cannot be raised with the present funds—setting aside, for the moment, the expense of furnishing, and the want of any income. But this is not the first instance of an attempt of this nature: the Royal Western Hospital, as it was pompously called, was, like the present undertaking, one originating in a private speculation; and it after a year or two was insolvent, those who had become Governors being involved in great trouble and litigation, *in consequence of being answerable for its debts.*

Even suppose that 5000*l.* were ready for the Gower-Street project, what would that do for the projectors? The Charing-Cross Hospital, the smallest at present in London, for its bare walls cost double this sum. But here is the Valetudinarium with not even half. This clearly shews that the public have taken no kind of interest in the matter; the money collected has been chiefly obtained in donations from those immediately and personally interested in the undertaking, and by the appro-

name was wanted for such a place in Justinian's time—a place in which diseases were to be cured—*Nosocomium* was the term adopted, and this has been the ordinary or the vulgar word for it ever since. But it would not do for "the University" of Gower-Street: their hospital is to be a *Valetudinarium*; and as they have christened it, so let it be called.

priation of a sum of money collected by other persons, and for a totally different purpose—namely, that of buying plate for the late Queen Caroline—a proceeding of which we scarcely know how to speak in adequate terms. That Mr. Hume, and a few others, who are shareholders in the University, and were concerned in the subscription in question, have consented to this we are credibly informed; nay, the *Times* (May 7th) states that the latter gentleman, who it appears was treasurer, has written to announce the fact of the donation, and adds, that one of the wards is to be called after her late Majesty. We can scarcely, however, think that a few individuals, so peculiarly situated with regard to the University, would venture on such a step, without the concurrence of the parties from whose pockets the amount was extracted, because any one of these might take legal measures against the parties so appropriating the proceeds. We presume, therefore, that the announcement is only intended as a feeler, in order to ascertain how far they may venture to go. But if it *be* true, then we think it was most unkind towards Mr. Hume, that any other than he should have been appointed to lay the foundation of the hospital; and we trust that another exhibition will be got up on laying the first stone in “Queen Caroline ward,” in order to commemorate so singular an act of liberality!

The paper above alluded to also informs us that the medical school “bids fair to be placed beyond the reach of detraction, or the necessity of praise.” Of course all are regarded as employing “detraction” who do not bolster it up through thick and thin; and we, who are neither blinded by love nor fear, and who will not be hoodwinked, but who choose to denounce humbug wherever we meet with it—we, who have watched the progress of this school, and noted its measureless pretensions,

its absurd and most groundless claims of superiority, as well as the overweening conceit and illiberal and unfair deterioration of others, adopted by some of its members—we, of course, will be set down in the list of “detractors.” But observe, they who use this language admit that it is not yet removed above the “necessity of praise,” and in this *necessity*, and in the determination “*to make a push*,” is to be found the only rational explanation of the system which has been adopted.

The *Times*, which, next to the *Lancet*, is the best authority on such matters, informs us that they expect to raise 1000*l.* by fees; so that, after all, they have, at the lowest possible computation, to procure 2000*l.* per annum in addition before the *Valetudinarium* can be maintained. But we beg pardon: one account states that the fees are to support the institution: 110 beds for a thousand pounds—something under ten pounds per man: we should like to see the diet table!

STATISTICS OF THE DEAF AND DUMB.

FRANCE, with its 32 millions of inhabitants, contains 20,189 deaf and dumb: that is to say, one in every 1585 of the population. In Russia the returns give 1 in 1548; the United States of America, 1 in 1556; for all Europe the proportion is as high as 1 in 1537. With regard to the education of the deaf and dumb, it appears that on an average throughout the whole of the civilized globe, not above 1 in 24 have the means of instruction: in France, however, the proportion educated is 1 in every 4. We take these facts from the third circular of the *Institut royal des Sourds-muets de Paris*, sent to all the establishments for the deaf and dumb in Europe, Asia, and America.

DECOROUS DOINGS OF THE CONCOURS.

STRANGE to say, the farce of the Concours for the chair of *Clinique interne* is still going on in Paris; but the candidates who have not thrown up their parts, are only amusing themselves,

when it comes to their turn to give a lecture—in lecturing their judges, and abusing them to their faces. M. Gilbert gave a *leçon énergique* of this sort last week, and was listened to with surprising patience. When M. Sandras, however, another hopeful concurrent, attempted to follow his example, he was called three several times to order by the president, but to no purpose: the proceedings had to be abruptly adjourned, amid volleys of hisses from the spectators!

CHARACTER OF THE LATE DR. BABINGTON.

[DR. BRIGHT, on commencing his lectures at the College of Physicians, which had been postponed in consequence of the death of Dr. Babington, premised them with the following eulogy on the deceased.]

I feel that an apology may by some be thought requisite for the alteration which has taken place, on my account, in the customary order of delivering lectures before the College, and yet, to the President, I need scarcely apologize; for, with a kind consideration which has ever marked his character, he readily, and almost unasked, yielded to the arrangement which was made, from the respect which I peculiarly owed to the memory of the late venerable Dr. Babington: the last effort of whose life was spent in the service of this College—for whose virtues we all feel equal admiration, and for whose loss we all feel equal sorrow; for perfect regret and perfect admiration admit not of degrees.

Sharers, then, as we all are in a sense of privation, I scarcely venture to speak one word upon a subject of such mingled painful and gratifying reflection, and yet am I unwilling to forego this opportunity of directing the attention of my associates towards that pattern of virtue which has passed away.

It would, indeed, be wrong to speak of one or of another as presenting the *finest* picture of a physician: men are formed in different moulds—each may be excellent in his kind; and it would be absurd in any of us to attempt a servile imitation of one individual, however perfect in our estimation. The laws of nature oppose the unnatural substitution; but it will do us all good to rest

our thoughts upon perfections which may thus become engrafted on our own characters, and amalgamated insensibly with our own dispositions; and as the aspiring artist wearies not in the study of the acknowledged masters of his art, so will the wise man seek constantly to impress upon his mind the prominent virtues of those whom he would imitate.

Would that I were able to depict the virtues of our departed friend! Scarcely do I feel myself worthy to attempt the task; because I *know* that my words are inadequate to *express*, and I *fear* lest my mind should be unable to *grasp*, one half his excellence.

His was a *sweet simplicity of manner*, which gave a moral grace to every action of his life—his a *profound humility of mind*, so marked, that, while thousands sought his aid as a pearl of inestimable price, he ever seemed unconscious of his own pre-eminence.

His was a *power of self-control* the most praiseworthy; readily, and what is far more, consistently, through a long life, rejecting all the allurements which the delights of the country, and even the charms which science itself held out to his innocent and ardent mind, because he felt the duty of industrious perseverance.

His was a *judgment the most correct*. His was a *benevolence of heart*, such as few have witnessed—an instinctive dread of inflicting pain, a delight in doing good. He had so trained his mind to kindness, that a quick answer or an ill-tempered word was never heard to escape his lips. Sorrow always found sympathy in his breast,—his hand was ever open to relieve,—and the register of heaven alone contains his daily acts of professional charity.

His was a *patient, pious resignation*, to the will of God; for God afflicts the upright man, and did most deeply afflict him; but he murmured not, and suffered not the rankling sorrows of his heart to interrupt his charitable course.

His was *parental affection*, most deep, most ardent, most judicious, most enduring. Years of separation diminished not the sacred feeling—even the death of his children seemed not to sever his communion with them; and his almost unconscious words betrayed that the last bands which held him to the earth were the delightful contemplations of the excellence of those who survived him.

His was a *strong perception and an accurate appreciation of virtue and of vice*; but his estimate of character was always tempered by Christian forbearance: free to praise the good qualities of others, he censured their faults as if he spoke under the combined impression that the failings of humanity are venial, and that his own judgment might perchance be warped by some erroneous view.

His was a *cheerful mind* and a most *delightful converse*: he justly estimated the value of social intercourse, and enjoyed it as a blessing sweetening the toils of life, and increasing the kindly ties which connect us with our fellow-creatures.

Ready to communicate knowledge to those who sought it, he was pleased to receive information from others, seeking it occasionally by exertions which scarcely seemed compatible with his arduous avocations and his advancing years.

Add to all this an *admirable skill in his profession*, founded on science, supported by a great natural sagacity and power of observation, which are acknowledged to have rendered him inferior to no man that ever lived in discerning and in treating disease.

A large portion of his time, in the earlier part of his career, was devoted to the acquirement and diffusion of scientific knowledge connected with our profession; and for many years his lectures on chemistry, and afterwards on the practice of medicine, delivered at Guy's hospital, charmed by their simplicity, while they bore the indelible stamp of that correctness of judgment which enhanced the value of the extensive information he possessed. His was not a mind to be blinded by prejudice, or to stop short in the pursuit of science; and if his more urgent and active occupations prevented him from entering on the field of original discovery, he ever kept pace with the improvements of the day; and, whether in chemistry or in medicine, was always ready to weigh with impartial care the importance of new results,—to delight in the brilliant discoveries of his friends and associates,—and with prudence to adopt such innovations in practice as approved themselves to his sound and unbiassed judgment.

In him was to be found an excellent example of that wholesome and yet

comparatively rare combination of knowledge, which unites our professional pursuits with the study of the natural sciences—which connects the physician with the philosopher; and careful as he was at every step not to interfere with what he acknowledged as the first duty of his life, he found time to gain for himself a well-merited reputation as an energetic promoter of the sciences of mineralogy and geology, at a time when they were in their infancy, and he may fairly be esteemed the chief founder of that society which, from the time when it first met under his roof to the present moment, has been supported by a succession of the most indefatigable investigators of the abstruse pages of nature's history which the present century has produced, every one of whom has felt a pride and satisfaction in cultivating the friendship of this excellent man—this ardent and intelligent participator in the interest of their discoveries.

Such are a few, a very few, and feebly-drawn characteristics, of this truly great man—this almost perfect physician, an honour to our College, an ornament to our profession. No man ever passed more hours in the conscientious discharge of duty;—no man by his personal exertions ever did more good;—no man ever acted less under the immediate impression of self interest.—The comeliness of virtue will ever be felt and acknowledged by all whose estimation is worth the good man's desire. With regard to our departed friend this has proved the case, for no man was ever more extensively beloved: no man's example has had more weight: to no one are we more indebted for supporting and exciting amongst us a high tone of moral feeling.

Such is the man whom the good delight to praise: such the physician whom the wise consent to honour: such is the friend whom we deplore: and long as a record of our profession shall exist, so long will his name be handed down as a bright glory on its pages: and ever will it be counted as a surpassing praise to the century to which he belonged, not alone that such a man existed, but that he was surrounded in life, and cherished in death, by hundreds whose breasts glowed at the contemplation of such virtues, and who wished, at least, to make them their own.

ON DOUBLE VISION.

BY M. PREVOST*.

"This imperfection of my sight," says the author, "is dated from 1823; though it still exists, I shall speak of it from my notes, almost all anterior to the present period, because the state of my sight no longer allows me to observe with all the exactness desirable the phenomena it presents." If M. Prevost views a point with the right eye, he instantly sees two; these two images are separated by an interval capable of measurement; in fact, in order to appreciate it, it is sufficient for him to compare with any object of known length, such as a printed letter (*caractère d'imprimerie*), a well-defined line, (*un trait bien limité*), &c.: at the distance at which he is accustomed to read, the distance of the two images appears to be half a line. But at such small distances it is hard to avoid some causes of error; in fact, according to the situation, one of the images becomes weakened, and may even become entirely effaced: the same eye which with the author is affected with a doubling of the object, is also affected with a tripling of it. From these two circumstances it may follow, that at different distances the two images are no longer the same. It is then at great distances that we can hope to determine with any degree of exactness the separation of the two images observed. This has been done by M. Babbage, one of whose eyes is subject, as that of M. Prevost, to double a single point.

When one eye sees two images of any one single point, these images being on one and the same vertical right line, we know that the upper image ought to correspond to a point lower down on the retina. This the author has directly proved. By causing a screen to move slowly from above downwards, he makes the lower image disappear before the other. It becomes gradually pale, whilst the upper acquires a deep tint, equal to that of the effaced image. Thus the doubling disappears by masking one of the images. This image may be masked naturally by the eyelid; the lower image by the upper eyelid; *et vice versa*. This species of natural screen is easily obtained by a mere in-

clination of the head. We have just said that the image masked by the slow and gradual movement of a screen becomes pale before it disappears. By successively diminishing the bundles of rays which come from the point to each of the two foci, and by graduating the movement, we cause the images to disappear by turns, and we meet with an intermediate inclination of the head or of the screen, at which the two apparent points are equally illuminated. The interval, which separates the two images from a black point traced on a white paper, assumes a yellow tint. In order to perceive it well, we must observe the doubling of a line. If we observe a coloured object of small extent, a small circle, or a small rectangle, it happens that we have the appearance of three tints by the effect of the double image. That takes place when the two images cannot be entirely separated. Where they remain confounded together, the tint is doubly strong. It is particularly in reading that the doubling of a small object is observed by M. Prevost; it may cause him to confound a 0 with the figure 8, but he rectifies this error with considerable facility, though this imperfection of sight causes him some embarrassment in reading. The doubling takes place on viewing the object with a convex glass—a line of three inches focus, for example. "On bringing the glass near the object, such as a black point on a white paper, I see," says he, "two points, one over the other, nearly as with the naked eye; if I bring the glass near my eye, the interval of the two images diminishes, and they may be even confounded. At this limit I see but one image much more distinct; still a sort of semi-transparent shade surrounds it; but this shade is not perceived without difficulty. In continuing to bring the glass near to the eye, two images are again formed, and the more I approximate it the more they separate: but they are not one above the other—they appear on a line almost horizontal; they are less distinct than the preceding, and soon become very confused."

M. Prevost then proceeds to inquire into the cause of this phenomenon. "Wherever this cause may be seated," continues he, "it produces two foci on the retina, to which the rays sent forth by one and the same point, meet. This may happen in more ways than one,

* Du lin Journal, No. VIII. from the Arch. Gen. Jan. 1833.

The simplest is that which places the defect in the crystalline lens. This organ ought to be, in this case, considered as a double lens. This effect may arise from a fracture, a bruise, a sealiness, or a partial flattening of the crystalline."

"The effect of a fracture is readily seen on a glass lens; it produces a double focus very apparent. It is to this cause that Wollaston referred a doubling of the image which he had occasion to observe; and in speaking of this affection of my right eye, he told me that he had caused a momentary disappearance of the doubling by viewing the object through the refracting angle of a prism. Again, such a separation of the focus may take place without rupture; it would be sufficient that one of the segments of the lens be inclined on the other, so that the crystalline, for example, undergoes a wrinkle or fold (*un pli*) in its texture. May not this organ, composed as it is of layers, be exposed to accidents of this nature? If one of the segments were more flattened than the other, their foci would not be the same; but in this supposition the foci would not be exactly of the same distance, and would not fall on the retina so as to form there at once two perfect and distinct images.

"In recapitulation, there are some eyes made so as to see two images of one single point. These two images, measured on the visual angle, have been found distant from each other twelve minutes of a degree. The cause of this phenomenon ought to be a disjoining or separation of the crystalline lens, by a rupture, or a fold, or perhaps a partial change of convexity."

To this extract from M. Prevost, we shall annex an analysis of a letter written to him by M. Babbage, who was attacked with a similar infirmity:—

"I see the two images of the objects vertically one over the other with the two eyes, or with each of them separately, every time I look at an object without forcing the organ. The upper image is weaker than the lower or real one, and is separated from it by an angle of twelve minutes. When I am in a bad state of health, the second image becomes stronger, but its angular distance is not altered, as far as I have been able to judge. (The state of health does not appear to have any influence on the phenomenon in question with M. Prevost.) By reason of the

small distance of the two images, the objects, when brought near, do not appear double, but an indistinctness is manifested on the edges. When I look through a small hole made in a card, or through a very small opening between my fingers and thumb, as I often do, in order to see more distinctly, I lose sight of the weak image; I can also free myself of it by leaning the head back, and directing my view under the eyelid, so that the ray coming from the object grazes it very closely. I see but one image on looking with one eye through a concave lens; I can also get rid of the weak image by frowning; but considerable exertion is required for that."

This defect of vision does not appear up to this to have engaged the attention of any physiologist. Cabanis, however, speaks of it, and says that he observed two instances of it*. C. Bonnet, in his memoirs on his life and writings, a manuscript as yet unpublished, speaks, on the subject of his diseases of the eyes, of a doubling of the objects by that one of his eyes which he had devoted to the microscope. We read in the memoirs of E. A. Holyoke, a physician of Salem, in New Jersey, who died in 1829, at the age of 100, that in the latter years of his life the objects placed at a certain distance were multiplied to his eyes so that he thought he saw four or five moons. Finally, in a note added to the memoir of M. Prevost, M. Arago informs us that his left eye presents to us all the phenomena described by the professor of Geneva, but with some circumstances which appear to him to modify the explanation given of them. He promises to return to this subject at another time.

MEDICO-CHIRURGICAL SOCIETY.

Tuesday, May 14, 1833.

Mr. Key on the Ulcerative Process in Joints.

A VERY full and valuable communication from Mr. Aston Key occupied the Society during the evening. The time barely served for the perusal of the paper, and as it seemed to be the wish of some of the members present to offer certain remarks on the views of the author, it was agreed that, on Tuesday evening next, an oppor-

* *Rapports du Physique et du Moral de l'Homme*, 2d edit. tom. 1, p. 525.

tunity for so doing should be afforded. Meantime we are enabled to present our readers with the following ample and accurate abstract.

The object of the paper is to illustrate the mode in which nature effects the process of removing the cartilage covering the articular surfaces of bones. The first part of it embraces a general view of the ulcerative process, as it occurs in the various textures of the body; and Mr. K. appears to think that the activity of the process, or the disposition to it, is mainly depending on the degree of vascularity possessed by the part. Thus, in highly vascular structures, as the mucous and similar membranes, ulceration is rapid; in less vascular tissues the ulcerative process is more slow in its course, and in some, as the serous membranes, the part undergoes a change of structure previously to ulceration taking place. Again, in parts endowed with the smallest degree of vascularity—as tendon, fascia, &c.—the tendency to ulceration exists in the lowest degree. Among the latter structures he ranks the cartilage of joints; and concludes, from his observations of the morbid appearances exhibited in joints, that the ulcerative process is in them depending on the action of the surrounding structures, in which the cartilage itself takes no share. He endeavours to establish an analogy between the absorption of cartilage and the removal of a dead portion of bone under necrosis. The appearance of the dead bone, and the vascular granulations from the interior of the new bone, furnish strong evidence that the absorption of the sequestrum is effected by the contiguous vascular structure; and the morbid appearances of joints also, he thinks, justifies the opinion he has advanced—that the neighbouring vascular tissues effect the removal of the cartilage in the various forms of disease under which the bone is found to be denuded.

The means by which the removal of the cartilage is effected, will vary according to the activity of the process and the nature of the disease which has given rise to it. Nature, he observes, seems to adopt four different methods of effecting her object.

The first, and most commonly observed, is the chronic form of disease; in which ulceration of the cartilage takes place, as the consequence of long-continued inflammation of the synovial membrane—as in the knee-joint of the adult; the complaint either commencing in an insidious form of chronic inflammation of the capsule, or in an acute synovitis, subsiding into a chronic form of inflammation. When abscess forms, and the cartilage is extensively destroyed, the following morbid ap-

pearances are found. The ulceration is found to commence at the edge of the cartilage, when the synovial membrane is fringed and highly vascular, and is observed to fit closely into the grooves of the absorbed cartilage. In other parts, a false membrane appears to be formed over the cartilaginous surface, and having its origin from the edge of the synovial membrane. This false membrane adheres to the cartilage, and is highly vascular: in the advanced stage of ulceration it is found to cover a very large part of the cartilaginous surface, and appears to be the agent by which the absorption of the cartilage is effected. In those parts where the whole cartilage is removed, and the surface of the bone exposed, vascular granulations arise from the latter, and inosculate with the false membrane.

To this membrane Mr. K. assigns other offices besides that of ulceration, namely, the production of pus in such cases as are attended by suppuration, and the important function of producing ankylosis, which would require a longer description than the limits of an abstract will allow.

The second mode is illustrated in what occurs under acute suppuration from wound of a joint. The rapid manner in which ulceration follows an accident of this nature prevents the development of the membrane, as in the former case, and a different process is therefore set up. The appearances in the ulcerated portion of cartilage is different: instead of being ulcerated at the edge, grooves are seen in different directions, and the corresponding portions of synovial membrane are furnished with a fringe of adventitious membrane, by means of which the removal of the cartilage takes place. Not a vestige of vascularity is observable in the cartilage under the most successful injection of the joint.

The third form of ulceration is that which ensues as a consequence of scrofulous disease beginning in the cancelli, as is frequently seen in the bones of children who have suffered from joint disease. A scrofulous degeneration of the cancelli takes place, sometimes ending in the death of a portion of bone. The ulceration of the cartilage, under these circumstances, takes place from its attached surface, and the same passive condition of the cartilage is observable as in the other forms of ulceration. Vascular tufts are seen rising from the cancelli of the bone, and, as it were, undermining the cartilage, while often the process is assisted by inflammation extending to the synovial membranes, and the same appearances are seen as in the first example.

The last form of the destruction of cartilage the author of the paper slightly ad-

verts to, namely, that in which the cartilage appears to degenerate into its elementary fibrous tissue.

In more fully illustrating these processes he takes occasion to notice the different forms of joint disease, especially the affection of the hip-joint, which he considers as beginning frequently in the ligamentum teres.

The paper is illustrated by drawings and preparations, which it is understood will be exhibited to the society on the next evening of meeting.

ROYAL INSTITUTION.

Friday, May 17, 1833.

Dr. Turner on the true equivalent numbers of Bodies.

In order to render this subject intelligible to a mixed audience, the lecturer was obliged to spend much time in preliminary matters. He gave a clear and popular account of the mode in which the combining proportions of chemical substances are expressed, and pointed out the advantages of the beautifully simple scale of numbers at present pretty generally adopted by chemists throughout Europe. But though sanctioned by the high authority of Davy and Wollaston, Berzelius, it appears, never was satisfied that the fundamental elements of the scale were correctly gathered, and to this hour maintains that the numbers in common use are not exact representatives of the proportions of quantities actually forming chemical compounds, but mere approximations, more or less probable. To the statement of certain chemists respecting the composition of chloride of barium, Berzelius makes his principal objection; and Dr. Turner has been enabled, from some recent researches, to demonstrate the propriety of the dissent of the great Swedish chemist. Dr. T. did not enter into particulars relative to his own conclusions, but we understood from him that they are to be speedily submitted to the scientific world through the medium of the press. It may be added, that the object of these new views is not by any means to overturn the popular system of noting the combining proportions, but to shew that it is not to be depended upon, as hitherto, as if it exactly expressed what happens in nature.

In the library there was exhibited an ingenious contrivance for shewing that the speed of four-wheeled carriages greatly depends upon the length of the perch and the height of the wheels.

TWO CASES OF ACCIDENTS,

FROM ADMISSION OF AIR INTO THE VEINS
DURING SURGICAL OPERATIONS.

SOME professional men have expressed doubts as to the accidental admission of air into the veins during surgical operations. Such doubts appeared well founded when the occurrence first attracted the attention of surgeons; especially on considering that veins about the neck were so very often wounded in the removal of tumors; and that some of them, as the external jugular, are frequently opened for the purpose of taking blood, without any unfavourable consequences.

Not long since, I had evidence of the existence of such cases in two of my own patients, within no great distance of time from each other.

CASE I.—Mr. William Burrill, of Salem, aged 60, was admitted into the Massachusetts General Hospital, on the 16th October, 1830. He had a cancerous affection of the left side of the face and neck, of the extent of three or four inches diameter. It was hard at the edges, of a livid red colour, ulcerated in the centre, very offensive, very painful, and had made an impression on the general health. The parotid gland, the submaxillary, the sublingual, and all the textures excepting the bone, were involved in the complaint. The lower jaw itself was thought to be diseased at first, but it afterwards appeared that it was not so. In so bad a state of things, I felt very little hope of being able to eradicate the disease, and would not have attempted any operation had not the patient solicited it.

Considering the extent of the disease, that important blood-vessels would be divided—namely, the facial and sublingual arteries, probably the temporal, and even the external carotid—I thought it best to begin by securing the carotid trunk. An incision for this purpose was begun opposite the thyroid cartilage, and carried two inches downwards. The platysma muscle was divided; the edge of the mastoid exposed and dissected. Thus far, only a few drops of blood were discharged. The face of the sheath of the great vessels was a little uncovered, when a small effusion of venous blood appeared under the knife, and checked the operation. At that instant a very distinct sound was heard, like the passage of air through water. A few bubbles were seen in the venous blood, the flow of which was immediately arrested by applying a finger on the part. The

patient exclaimed, "I am faint." On regarding his countenance, it was not pale, but livid, almost black, and the muscles agitated by a convulsive motion. The respiration became deep, laboured, and stertorous, like that of apoplexy. Committing the compression of the vein to Dr. Hayward, who assisted me, I examined the pulse at the wrist, found it distinct, but very slow. The wound not bleeding, and very little blood having been lost, I directly opened the temporal artery, and the blood poured from it with great freedom. As it flowed, the respiration became more frequent and less laborious; the pulse at the wrist more natural. The leaden colour in the cheeks assumed a reddish tinge; and the alarming character of the symptoms was evidently diminished. About twenty minutes elapsed during these changes. At the end of half an hour, I judged it safe to remove the patient to his bed, where he lay in a state of insensibility for two hours; at the expiration of which he awaked as from sleep, still breathing like an apoplectic. The night was passed without any accident, and on the following morning he was as well as usual, with the exception of a moderate soreness over the thorax, and a headache.

In seven days after the accident described above, the operation was performed without tying the carotid artery.

The diseased parts were included in an elliptical incision, extended from the lobe of the ear to the upper part of the neck, and including the submaxillary, the sublingual, and parotid glands, all of them in a morbid and disorganized state. The os maxillare inferius was not diseased. The hæmorrhage was copious, but readily arrested, with the exception of that from a large vein, which, from its depth under the jaw, could not be distinguished so as to admit the application of a ligature, and was therefore compressed by a sponge. The veins below the wound were compressed by Dr. Hayward during this operation. The patient experienced a slight faintness, which soon passed off. He had no bad symptoms, and on the 10th of December, the wound being nearly healed, he requested his discharge, which was granted.

CASE II.—Nancy Bunker, of Trenton, in Main, married, her age 33. Three years since, she noticed a hardness in the right breast, which increased till it involved the whole gland in a tumor, very hard, moveable, yet obviously connected with the pectoral muscle by a morbid adhesion. The nipple is drawn in. The axilla is occupied by a considerable tumor, of a globular form, and quite hard. The disease has

been accompanied, during the last year, with very constant lancinating pains. The patient is desirous of an operation; has a strong conviction that she shall not recover, yet is perfectly tranquil and resigned.

Operation.—The patient sat in a chair. The right arm was extended, raised above a horizontal line, in order to give tension to the skin, and permit access to the armpit, and was supported in this position by an assistant. The skin on the surface of the breast, with the diseased nipple, were included in an oval incision; the breast was dissected from the pectoral muscle, and left connected with the axillary glands, while the extirpation of these glands was effected. As they adhered to the great axillary vessels, they were cautiously detached by dissection, and by insinuating the finger, where the cellular substance was loose, between the tumor and the great vein. This separation was nearly effected, only a slight connexion still existing at either extremity of the tumor. Proceeding to separate it, at the outer part of the axilla a vein was divided, and a small quantity of venous blood discharged. This obscured the parts at that point, and the knife was therefore carried to the other extremity of the tumor. Scarcely was this done, when the patient struggled, and, on regarding her, I perceived her complexion to be a livid pale colour; and at the same instant the bubbling or clucking noise was heard, though indistinctly; but the place from which it issued was not visible, the surrounding skin and fat having fallen over it at the moment of the transfer of the knife. Directly the axilla was compressed, the patient became insensible, breathing in a distressed manner, as in apoplexy. The tumor was at once separated. The posture of the patient was changed, and she was supported by those around. Some brandy was poured down, and ammonia was introduced into the nostrils. The pulse, however, became less distinct every hour. Cloths dipped in hot water were thrown over the extremities; strong frictions were applied to the chest and to all parts of the body; considerable quantities of brandy were again poured down the throat. At this moment the livid colour of the cheeks gave place to a suffusion of vermilion red, and no glow in the cheek of a youthful beauty ever gave one so much pleasure as that flush. I was turning to the class, who watched the different operations with intense anxiety, to say, "the danger is over!" but checked myself, and continued the efforts. But the flush soon passed off; the lividity re-appeared; the respiration became more feeble; pulse at the wrist scarcely perceptible; and, not-

withstanding the redoubled applications of external heat and moisture, the extremities and whole body cooled rapidly, and presently the respiration ceased.

As a last effort, I opened the larynx, and put in operation the inflation of the lungs by a bellows, in a very speedy and perfect manner, imitating the movements of inspiration and expiration with great exactness, continuing the general application of heat and frictions to the whole surface. These administrations were continued for about twenty minutes longer, without any encouraging appearances. At the end of this time I perceived there was no remaining hope of the restoration of my patient to life. The friends being anxious to take advantage of a vessel then sailing for their home, the body was soon after removed, and no opportunity afforded for examination.

The effects of the entrance of air into the blood-vessels appear to have been known to Lieutaud, Morgagni, and other distinguished pathologists; but the danger of such an occurrence in surgical operations does not seem to have been adverted to, until the operation of M. Dupuytren, in which the admission of air through the external jugular proved suddenly fatal. Since the publication of this fact, the occurrence has presented itself to many surgeons in Great Britain and this country.

A natural scepticism in regard to these accidents has arisen from, not considering the peculiar action of the auricles of the heart. How, it is asked, can air force itself into the veins, which are already filled with blood, and at the moment this fluid is discharging itself from an aperture in the vessel? The possibility of the accident will however be admitted, on recollecting that the auricles act not only like an expelling syringe, when they drive the blood into the ventricles, but that they have the power of suction when they dilate themselves, thus sucking the blood from the two cavæ, and, of consequence, from the great veins connected with the cavæ. This suction power of the auricles explains what would otherwise be unintelligible, the movement of blood through the large inactive veins near the heart.

There remains another difficulty. Why do not the sides of these veins collapse when the blood is pumped from them by the auricle? and if they do thus collapse, how can air be drawn in through a small aperture in one of these vessels? This objection has been removed by M. Bérard, who has shewn that the large veins near the heart are protected by fasciæ, connected to the coats of the veins by cellular substance. The fasciæ themselves are attached to bones, in such a way as to pre-

vent their collapsing on the veins. Further, it may sometimes happen that the coats of a vein assume a morbid structure, which gives them an unhealthy rigidity, and in this manner prevents their collapse. This occurred to M. Dupuytren, as I am informed by my friend Dr. Lodge, who was in Paris at the time. M. Dupuytren, being about to divide a large varicose saphena vein, expressed some apprehension that air might be admitted, and that the result would be fatal. The vein was divided, the peculiar sound of the entrance of air was heard, and the patient expired.

In the first of the cases above related, the vein opened was a small vein crossing the neck from the median external jugular to the great internal jugular. At least I presume this to have been the vessel, though there can be no certainty of its identity, the incision in the neck being small, the parts not much uncovered, and the sheath of the internal jugular not opened. This small vein, stretched across the neck, was kept tense by its attachment to fixed veins at each extremity, and would thus be in a favourable position for the admission of air on the suction of the auricle.

The vein opened in the second case was the subscapular. It did not seem to be large, though perfectly visible before it was cut, and the point of the incision was at a sensible distance from the great axillary vein, say nearly an inch. The dissection had separated it from the surrounding parts in a considerable degree. The axillary cavity was extremely dissected; so that the attachments of the fasciæ covering the great vein must have been much relaxed.

Here then was a small vein, at some distance from the heart, dissected from the surrounding parts; and its receiving vein also dissected. The coats of the vein were not visibly diseased; the explanations of M. Bérard will not therefore apply. The cause of the phenomenon in this case is to be sought in the position of the arm. The limb was extended and elevated; in consequence of which the axillary vein was in a state of extreme tension. The subscapular vein was also kept tense by the chain of axillary glands, and by the weight of the depending breast—for this organ had not been separated from the glands—in order that they might be drawn down by it and exposed.

The possibility of these accidents under circumstances like those above, where there could be so little reason to fear them, must be a cause of anxiety to operators, in the removal of tumors from the neck and arm-pit; and I know of no effectual means to guard against them. Pressure on the vessels intervening between the disease

and the heart would often be impracticable; and, where it could be applied, the tension of the fasciæ would generally render it abortive. Causing the patient to expire the air from the lungs, could only be practised for a moment. *Change of position*, by relaxing the vessels, would do something; yet the state of tension must in many cases be resumed, in order to carry on the operation. The immediate compression of the vessel on the appearance of the accident, might sometimes save the patient from death, though not from very threatening appearances; for, in the first case, the patient's life was preserved; but although the accident was instantaneously arrested, he was saved with difficulty.

On a view of all these considerations, it appears prudent to suspend an operation in the vicinity of the heart, at the instant of the appearance of venous blood from a suspicious point, and to compress the vessel, that time may be had for observing whether dangerous symptoms are likely to arise; and if these actually appear, we should directly resort to the means spoken of:—1st, compress the orifice of the bleeding vein with the utmost care; 2d, apply pressure on the veins between the wound and the heart; 3d, relax the part in which the vein is seated; 4th, the patient may be directed to expire the air from his lungs.

The means to be pursued for saving life, after air has been admitted, have been stated in the history of these two cases, and I know of none more effectual than were adopted. The opening of the temporal artery gave great relief to Case I.; it was not resorted to in Case II., because the patient had already lost as much blood as she could spare during the operation.—*Paper by Dr. Warren, of Harvard University, in American Journal of the Medical Sciences.*

MEETINGS AT THE COLLEGE OF PHYSICIANS.

WE gave no report of the last conversation, because no paper was read. We are happy to learn, however, that at the next meeting an essay is to be read by Sir Henry Hallford, and that His Royal Highness the Duke of Sussex, and other distinguished persons, are expected to be present.

TAX ON ANATOMY.

IN the Memorial relative to the Anatomy Act, and addressed to Lord Melbourne, which we published last week, there is a

sentence standing in the second column of page 206, which should have been printed as follows:—"By submitting to the Tax which your Lordship has thought fit to propose to them, they (the members of the medical profession) would appear to buy off from the government a legal degradation, disgraceful only to the legislature which imposed it, and might be supposed to admit an imputation as attaching to them, from crimes for which they of all others are least responsible."

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

—
DISEASES OF THE CHEST.

—
ACUTE PLEURITIS.

I now proceed to speak of diseases of the pleura, and in the first place of the most common affection of it—*inflammation*.

General Symptoms.—When the pleura is inflamed, there is of course pyrexia. If it be idiopathic—if it be consequent on some local irritation—it usually begins with shivering, and is followed by quickness of the pulse, and all the symptoms of pyrexia. The pleura is a serous membrane, and therefore, in most cases, you have a firm, hard pulse—not invariably, but generally. Then, as to the local symptoms, you have almost always severe pain—an acute, stabbing, sharp pain, the least attempt at a deep inspiration augmenting this exceedingly. This pain is not increased on the least pressure: you may press the integuments down upon the ribs without aggravating it, and you may press moderately between the ribs; but if you press very firmly between them, and still more firmly upon the ribs themselves, you of course will press upon the pleura, and then the pain will be increased. In severe cases there is extreme pain, so that hardly any pressure can be borne, and I have known persons unable to lie on the side, on account of the pressure exerted by the part against the bed; a case must be very severe for there to be pain on slight pressure; in truth, you may generally distinguish pleuritis from rheumatism of the

muscles of the chest, among other means, by this—that in the latter case the least touch causes pain and soreness; such a pressure as will not affect a patient labouring under pleuritis—pressure on or between the ribs and at the back or front of the chest. There is in acute rheumatism, for the most part, profuse sweating, such as there is not in pleuritis; but there is not in rheumatism that general disturbance of the constitution which occurs in pleuritis. In pleuritis the whole constitution is very much disturbed, and there is not that severe pain by any means that there is in rheumatism. In general you make out the difference of the cases very well. The pain in pleuritis is only felt at the lowest part of the chest, or at least low down in the chest, not in front, nor at the back, but to the side. I suppose the disease has had its name *pleuritis* from the pain being observed to be situated in the side, and not from the pleura being inflamed.

The respiration is rapid in this disease, because the patient cannot make a deep inspiration, and to compensate for the want of depth, he breathes the more quickly. The pain is increased by coughing, and it is also increased by speaking. Sometimes patients cannot speak at all on account of its severity.

In general we make out the nature of the disease sufficiently without listening to the chest. This affection is one of the best marked of any with which I am acquainted. There can be no difficulty, except in distinguishing it from rheumatism; and, in general, if you attend to the points to which I have just referred, you will not meet with any difficulty even on that head.

The seat of the pain will sometimes vary in the course of the disease. It will sometimes cease on one side, and be felt by the patient on the other; and now and then it is said that the pain is not felt in the part which is found inflamed after death. The pain is felt in the opposite side during

life, and opposite to that in which we find marks of inflammation after death. It is said, but I do not recollect seeing such a case myself, that sometimes no pain has been felt at all, and the practitioner has been surprised to find at the autopsy violent marks of inflammation. Usually the patient lies best on the opposite side; but sometimes he can lie easiest, or lie only, indeed, on the affected side. The cough which attends this disease is usually dry, and not very frequent; and sometimes it is altogether absent.

Auscultatory Signs.—On listening to the affected part, you find less respiration there in general than there should be. The part is not much expanded in respiration: you observe that the ribs there do not move so much as in other parts of the chest that are healthy; less respiration occurs there, and therefore on that account only there would be less respiratory murmur; but there is sometimes considerable effusion produced of lymph or of serum, and that of course will obscure the respiratory sound. After a time, effusion takes place in a decided manner, and then you have a dull sound upon percussion, and no respiratory murmur is heard at the part. There is no crepitous rattle heard, as in peripneumonia; no sonorous or sibilous rattle, as in inflammation of the substance of the lungs; and therefore with this, and the acuteness of the pain, there is in general no difficulty whatever in saying that the patient is labouring under inflammation of the pleura. Now and then you will have pleuritis united with peripneumonia and bronchitis, so that you have crepitous rattle as well as acute pain, or you have sonorous and sibilous rattle; but the acute pain, which is unknown in peripneumonia and bronchitis, sufficiently shows that those affections are complicated with inflammation of other parts.

Morbid Appearances.—If you inspect the part after death, you find nothing more than I mentioned when speaking of inflammation of serous membranes in general. Sometimes there is diffused redness, sometimes there is a striking redness, and an effusion of lymph on or within the pleura, and sometimes there is serum occasionally quite clear, but for the most part turbid, and of a yellow colour, with more or less flakes of lymph swimming in it.

Causes.—The disease arises in almost every instance from cold and wet. It will sometimes arise from a local source of irritation; for example, from wounds, from the effusion of substances into the pleura, from ulceration of the part; but by far the most common circumstance of all is the application of cold.

Treatment.—The treatment I need not dwell upon; it is nothing more than that

for any common inflammation: bleeding, mercurializing, starving, and purging, will cure it just as easily as any other inflammation.

Ægophonism.—When, however, effusion takes place, you may always ascertain it to a certainty. Sometimes the patient loses his pain, may say he is a great deal better, but notwithstanding that, if you listen to the chest, you may ascertain that he is in considerable danger. Indeed you may in such cases be satisfied, from the quickness of the respiration, or the difficulty of it, that all is not going on well, notwithstanding the patient declares himself better. But if in every case of pleuritis you make a point of examining the chest by the ear, you will ascertain to a nicety when effusion takes place, and to what extent it has occurred. In cases unattended by danger altogether, you will observe this effusion, although a person who does not use his eye would not know that it existed. When effusion is present, there is a dull sound on percussion, and a want of respiratory murmur; and besides that, if the effusion be inconsiderable, you have in most cases a very peculiar phenomenon, and that is, that when the patient speaks the noise resembles that of Punch—a sort of nasal twang; just as though you heard Punch at the time, and which makes you laugh. You would fancy there was a showman near, speaking for Punch. It is a sort of cracked sound, and is sometimes silvery and vibrating; but the general description is, that it is a nasal twang, something like the voice of Punch. This is heard much better in general at the back of the chest than at the front, and as long as this exists you may be sure that the effusion is not very considerable. When it becomes considerable, you have not only a complete dull sound on percussion, and a want of respiration, but you do not hear the voice at all in the part—the echoing through the tube is not to be heard at all; but if fortunately the effusion should decline, then as it does so you will hear this peculiar sound again. It is something like the bleating of a goat, and is called *ægophonism* from *φωνη*, sound or voice, and *αἶς*, a goat, the sound of a goat. I think when you have once heard this, you can never mistake it again. It is a sound which but few persons have heard, because in general people do not listen to the chest in this disease; and when it is heard, it is only in a moderate, not in great effusion. The symptoms at large are not severe at the moment it may be heard, and therefore those who are not in the habit of using their ears in this particular disease, do not think it worth while to examine the chest at that period. You will hear it much the best by applying the stetho-

scope firm to the chest, and then your ear but lightly to the stethoscope. You do not hear the voice run through the tube as in pectoriloquy; it does not by any means take place to the same degree; it rarely, indeed, enters the tube at all, and much less does it seem to pass through the tube. There is no difficulty at all in learning these signs; you have only to hear them once, and you will remember them again. Laennec says, that he noticed it in every case of pleuritis that he examined for five years preceding the publication of his second edition. Where the effusion is very moderate indeed, then it is not sufficient to produce the sound; and if it be excessive, the phenomenon cannot take place in the least. He says that he has observed it where there did not exist in the chest above three or four ounces of fluid. It will occur not merely when there is a serum effused in the pleura, but it will occur in common hydrothorax, and when the serous membrane pours forth pus, as you know that it sometimes will. Altogether it is a variable symptom, because it can only occur when the effusion is moderate.

This phenomenon is explained by Laennec to be the conjoint circumstance of the compression of the bronchial tubes by fluid, and the transmission of the sound of the voice through a thin layer of fluid. If the layer be very thin it is not sufficient, the sound must pass through a certain body of fluid, and indeed a very thin portion would not be sufficient to compress the bronchial tubes. It must amount to a certain degree, both to compress the bronchial tubes and to be the medium of this sound; for if there be great effusion, the bronchial tubes are so compressed that there is but little air in them, and then the sound cannot be heard. Whether Laennec's explanation is correct I will not pretend to say.

If you change the level of the fluid, you will change the seat of the oegophony. If the patient be upright, it will be of course over the highest portion of fluid; but if the patient be lying down, then you will hear it where the layer of fluid is the thinnest. If the patient lie down, you will not hear it where there is a great collection, but at a higher point, where the layer of fluid is thinner.

CHRONIC PLEURITIS.

Pleuritis is sometimes a chronic affection, and here it is that this particular sign of oegophony is essentially serviceable. When pleuritis occurs in a chronic form, it is every day mistaken for phthisis. I have seen instances of this over and over again.

Symptoms.—Sometimes the acute form of the disease degenerates into the chronic,

but more frequently it is a very insidious affection, creeps upon the patient slowly, and the general symptoms so much resemble consumption that he is supposed to have gradually fallen into that affection; for this chronic form of the disease is frequently attended by no pain, or only by obscure pain, and yet the patient shall have pyrexia, cough, and expectoration. He will become hectic, will waste away, the pulse will be constantly quick, and he will die. On opening the body, a large quantity of pus will be found in the pleura, while the lungs themselves, perhaps, are entirely sound. Frequently, it must be allowed, in this chronic pleuritis, the lungs labour under phthisis: very frequently when it exists, tubercles exist in the lungs at the same time; but frequently they do not, and at any rate if they do, it is very common for the pleuritis to have been the sole cause of death, none of the tubercles having proceeded to ulceration.

In this chronic form of pleuritis, adhesions are not formed to any great amount. In the acute form, the effusion leaves adhesions; sometimes you find the whole side coherent—the pleura pulmonalis and the pleura costalis; but in this chronic form the collection is often altogether, or the greatest part of it, pus, and any adhesions that form are frequently slight portions of lymph that are effused, so soft that they are not capable of becoming organized, but being mixed with serum, you find, after death, that the two substances are united, or at least the one exists in the other. This fluid, this turbid serum or puriform serum, or this absolute pus, augments daily till the lungs are compressed towards the spine and towards the mediastinum; and sometimes they are so reduced that a careless examiner has said that they have disappeared altogether. Just as careless examiners in former days said that in hydrocephalus the brain was destroyed, and a person had been living for months without a brain, so the lungs have been compressed to such a degree in this disease that their existence has been altogether passed over.

Empyema.—Sometimes the affected side of the chest grows large; and if it be the left side in which the disease resides, the heart is pushed to the right, so that it beats on the right instead of the left side. The disease is then called *empyema*, if the fluid be pus, but it makes no difference whether it be pus or serum. You may have the heart, if the left side be affected, pushed entirely to the opposite side of the chest, and the ear may not be necessary in order to recognize the disease in these circumstances; for you may see the side increased in size. It appears to the eye to be larger than the other; and on measuring it, you

find one side of the chest, perhaps half an inch, or an inch, larger than the other. Sometimes you can discover fluctuation just as in other instances of a collection of pus; but now and then there is no enlargement of the chest, and no fluctuation to be felt.

In these cases, the want of sound on percussion, and perhaps the presence of ægophonism, will show the nature of the disease; but the want of all hollow sound on percussion, together with the history of the case, will, in general, sufficiently show it, without the occurrence of ægophonism. Ægophonism certainly does now and then occur, but still it is to be remembered that if the fluid fill up the side of the chest, or nearly so, you cannot expect this phenomenon. It is only in a moderate collection that you will have this sign, and therefore a person may have the pleura full of pus without it; but if you have attended the patient from the beginning of the complaint, and from the beginning have been in the habit of noticing all the symptoms to be learned by the ear, in conjunction with the general symptoms, you will easily find that ægophonism has appeared and disappeared; and while it has been disappearing, you know it has not been from an absorption of the fluid, but an augmentation of it, from this circumstance, that pectoriloquy of the chest gave a dull sound just in proportion as the ægophonism declined.

Evacuation of the fluid.—In this particular form of the disease, the making of a correct diagnosis is very essential, because you may render a patient essential relief; you may save life, and in those cases in which you cannot save it, you may protract it. It was only two years ago that I had a case of this description in a young child almost at the breast. The heart was pushed so much to the right side that it was pulsating there; and the nature of the case being perfectly clear, a lancet was plunged in two or three times, and the child fortunately recovered, and is alive now. An operation is always safe in these cases. If the collection should point at a particular part, that is the spot at which you should make the opening; but if not, then you should puncture between the eleventh and twelfth ribs. If you be in any doubt about the case, I should advise you to use a needle which has been invented by Dr. Davis. He has had a large needle made with a groove, which you may put into the side without any danger. When it is plunged in, if fluid exist, you will see it form a drop near the end of the needle. Whether there be water present or pus, it will escape to a certain extent; and if a drop of fluid come, you will be sure of the nature of the case. A small

trochar may then be passed in, and you may draw off the fluid. It will be right not to draw off much at a time, only to draw off what you consider a third or a half of what is there, according to the size and age of the patient; and you may continue to draw it off till the chest is completely emptied. It has been the custom of Dr. Davis, I know, to pass in a piece of hollow bougie, and there let it remain. The end of the bougie must be bent down and fastened by straps of adhesive plaster, so that it may not find its way to the chest. Something must be put into the end of the bougie to prevent the fluid from escaping too suddenly: the plug may be taken out, and a little fluid allowed to escape every day. Where the lungs are sound, the treatment has been successful. I have not seen many cases of this description, but Dr. Davis, of the London Hospital, has had several, and now he can count up a considerable number where life has been entirely saved by this method.

Auscultatory Signs.—When effusion takes place, there is a dead sound on percussion, and no respiratory murmur is heard. This is the natural result of the part being no longer filled with air, but with pus, which has driven it aside or upwards, and compressed it below. When a lung has become solid from air, you have this same auricular phenomenon. If the lung become solid from inflammation—if the substance be converted into something like liver, so far as the solidity is concerned—you must have a dead sound on percussion, as if fluid were there. No more air exists in the lung when it has become solid than when fluid abounds in the chest, and under these circumstances you have equally no respiratory murmur, because the lung being solid, it is unfit for its functions. But when a lung thus becomes solid from inflammation, it becomes so solid throughout that there is no respiratory murmur at the root of the lung, for that part is equally inflamed with the rest; if, however, the dull sound of the chest and the want of respiratory murmur arise, on the other hand, from a collection of fluid, it rarely so compresses the lung but what you may hear respiration at the posterior part; that is to say, about three fingers breadth along the sides of the spine from the vertebral column. Respiration also continues there when fluid is collected. I believe that, however great the effusion may be, even if the lungs be so compressed as to be found with difficulty after death, not presenting themselves at first, still respiratory murmur is heard at the back and root of the lungs, in the situation I have just stated. This murmur, too, is heard before the effusion is very considerable, and it is

heard for a length of time under the clavicle at the highest part of the chest. The collection of fluid does not mount so high, but that for a considerable time you may hear the murmur immediately under the clavicle. When the want of hollow sound on percussion and the want of respiratory murmur arise from the lung becoming solidified through inflammation, you may very rapidly cease to hear respiratory sound under the clavicle; the inflammation may be so quick in its operation, and solidify the lungs so soon, that you may hear no respiratory murmur on either side of the spine, because all parts of the lungs may be inflamed: but when the want of a hollow sound on percussion and the want of a respiratory murmur arise from effusion compressing the lung, it is a long time before they are lost at the upper part of the chest under the clavicle, and at the very last you will always hear I believe the respiratory murmur at the back, about three fingers' breadth on each side of the spine.

The part of the chest where you should first listen for that peculiar phenomenon of the voice called *œgophony*, is from about one to three fingers' breadth from the lower angle of the scapulæ to the nipple. The reason why you most frequently hear *œgophony* between the lower angle of the scapulæ and the nipple is, because it is below this that the fluid generally accumulates; and if the whole lung be covered with effusion, still the thickness of the body of the fluid is always less at the posterior part. You can hear this phenomenon here when you can hear it no where else, because in this situation the fluid cannot accumulate so extensively as at other parts.

After the phenomenon has declined in the front of the chest, from the great accumulation of fluid, you will still hear it at the back in that particular part.

In mentioning to you that the accumulation of the left pleura sometimes pushed aside the heart, so as to produce the extraordinary phenomenon of the heart beating on the right side—the man, however worthy, no longer having his heart in the right place—I might have stated, that before auscultation was known, at any rate after percussion had been introduced to the medical world, but treated with neglect in this country, I saw a case that puzzled me completely. It is many years ago, and I should not be so puzzled now. In a case of this disease, the liver was so pushed down that it was felt below the navel, and I being young in practice (though, however young a practitioner might be now, he could not make such a mistake) had no idea of the nature of the disease, and supposed that the man had

an enormously enlarged liver, and so did every body else that saw him. The man had a very enlarged abdomen, the liver could be felt as low as I have stated, but after death that organ was found perfectly healthy, but, like the heart in other cases, it was not in its right place. A vast accumulation had taken place in the right pleura, which actually pushed down the diaphragm, and consequently pushed down the liver; so that the case was completely misunderstood. If auscultation had been then devised—if all the phenomena had been known then that are known now—the matter would have been very clear. We should have found that there was no enlargement of the liver from this circumstance—that there must have been a dull sound on percussion, all up the right side of the chest, and, on listening for respiration on the right side, there would have been none heard: it would have been perfectly clear that the right side of the chest was occupied with something else instead of air, and, if the case had been observed throughout, of course there would first have been noticed *œgophony*, the bleating sound, and afterwards it would have disappeared; so that no mistake could have been made. An operation might have been performed, and the man might have recovered; but as it was, he died. There was a large collection of liquid in the right side of the chest, and every one was quite surprised to find it there. I was not at the inspection, but such was the result; so that an accumulation in the right side of the chest may push down the liver in an extraordinary manner, just as an accumulation in the left side may push aside the heart. By the careful use of the ear, the nature of the case, as I have already observed, might have been fully cleared up; and every day, even now, cases of chronic pleuritis are mistaken for phthisis.

In this chronic form of the disease, as the accumulation takes place slowly, respiration is not so difficult as you might imagine. The other side of the chest gradually does more and more duty, and the patient feels the inconvenience increase so gradually, that it is not such a source of distress to him as you would imagine. In acute pleuritis, when the effusion is very considerable, respiration is necessarily rapid; and there you have infinitely more difficulty of breathing than if the same quantity of fluid were effused in a chronic form. This is nothing more than an instance of a general fact, that when any thing peculiar comes on slowly, and is increased moderately, it is not productive of half the excitement that it would be if it came on quickly.

Compression of the Lungs.—When the fluid

has thus compressed the lung, although nature may cause its absorption, or although a medical man may occasion its escape by an operation, it is possible that the lungs may never expand again; and this want of expansion may occur either from the great compression that they have undergone, or from the production of such firm adhesions that they are effectually bound down. Inflammation may not only have induced the accumulation of fluid, but may have produced such an effusion of fibrin as to form firm bands, binding down the lungs; and from either of these circumstances the lung may never recover. Laennec declares that he has uniformly found, on inspections, these extraordinary firm adhesions, and he calls them *fibro-cartilaginous*—not fibrous, as we generally see adhesions, but fibro-cartilaginous. However, as the lungs have been known to expand again in some degree, and the chest, which was sunk in, in consequence of the compression of the lungs, has in some degree recovered its form, we can hardly suppose the lungs in every case to be prevented from expanding merely from adhesions. Of course, if the lungs will not expand, the chest will become flattened on the sides by the pressure of the air; but it has been known that the chest, after it has become flattened, has enlarged again, from the lungs having recovered their powers; and if the want of expansion in the lungs for a great length of time, arose from fibro-cartilaginous bands, it is not likely that they would ever yield so as to allow of the expansion of the lungs again. I confess myself, that the extreme compression of the lungs seems to me to be quite a sufficient cause for the want of their subsequent expansion, without having recourse to the supposition that in every case where they do not expand again there must be firm adhesions. The whole lungs are so compressed, they are so squeezed together, and become so fixed, that they resemble muscles—muscles with fibres too minute for detection; you would think they were muscles with exceedingly fine fibres; and I may mention that when the lungs are so compressed the colour is either red or grey.

Contraction of the Chest.—If the lung have been so compressed that it will not expand, and the fluid has been absorbed or let out, and no more has formed, the ribs on that side fall and lie closer together than they should do; the shoulder on that side falls below the other, and the muscles (especially the pectoral) waste, both as to breadth and as to length. The muscles waste in proportion as the side becomes contracted, and they are found after death to be diminished on actual measurement,

and still more do they appear to be diminished to the eye. Even the spinal column at length inclines, in some cases, to the opposite side. Most practitioners must have seen instances of persons with their ribs lying close together on one side, with the shoulder depressed and the spinal column bent to the other side: the nature of such cases, however, was not understood, nor was the general phenomena of the case itself well described, before the appearance of the first edition of Laennec's celebrated work. I recollect very well having had an individual pointed out to me, as a decided proof of the power of muriate of lime in scrofula and phthisis. After suffering very long from pectoral complaints, and being put under the long exhibition of muriate of lime, the man recovered his health; but one side of the chest was manifestly smaller than the other, and he was shewn to every body as a man who had long had phthisis and had wasted away, but all the ulcers had healed up by the power of muriate of lime. It was considered that the lung had wasted simply by ulceration, and the contraction of the side of the chest was thought a sufficient proof of it, because he had expectorated continually from irritation of the bronchiæ; and it was also thought that the ulcers had been completely healed by means of the medicine. I supposed, not knowing better (for nobody knew better in those days), that this was actually the case, and therefore did not attempt to deny it. There is no doubt whatever, now, that this was not a case of phthisis at all, but a case of chronic pleuritis, in which great effusion had taken place; which effusion had afterwards been completely absorbed by the power of nature, and the lung had never been able to recover itself from its compressed condition. You will see, in Laennec's work, a drawing of an individual with one side of the trunk lower than the other, through the falling in of the chest in the manner that I have now described.

Laennec considers, that when a case of this description is well marked, it arises from that form of pleuritis which is attended by hæmorrhage into the pleural cavity. It so happens, that when the pleura is inflamed, sometimes an effusion of blood takes place into it, just as occasionally occurs from mucous and serous membranes. I mentioned, when speaking of hæmorrhage, that these membranes will produce an effusion of blood; why, we cannot tell; but sometimes it is the case: there is, however, no apparent reason for it. This sometimes happens in the case of the pleura; blood is effused, and Laennec considers that it is in such in-

stances that this extreme compression takes place. There is, however, no proof that it *always* results from hæmorrhagic pleuritis; sometimes it arises from that source, but sometimes I am satisfied that there is no hæmorrhage in pleuritis: on the contrary, when the fluid has been let out, it has been proved to be mere pus, without any admixture of blood; and yet contraction of the chest has occurred, just as where blood has been let out in conjunction with the pus. If it occur more frequently (as Laennec says) after hæmorrhagic pleuritis, and these dense fibro-cartilaginous bands, formed by a cohesion of the fibrin in the pleura upon the costal pleura, were always discovered in contraction of the chest, I should still not regard the thickness of these bands of fibrin as the cause of the contraction, but as effects, no less than the contraction itself, of the inability of the compressed lung to expand again.

Bloody fluid, just like pus, is not so rapidly absorbed as mere serum; the lung is irrecoverably compressed when blood is effused by the duration of the pressure, and from the slow manner in which the elasticity of the chest, and the pressure of the atmosphere—resisted as it is by the natural structure of the chest, can bring down the side to the flattened lung, a space probably exists, greater or smaller, for some time. Laennec, indeed, seems to contradict himself, for he says that he is of opinion that contraction of the chest may be found in an equal degree after the disease has produced merely cellular adhesions; so that in some parts of his work he seems to give up the opinion that the inability of the lungs to recover always arises from these firm fibrous cartilaginous bands. He also allows, in another part of his work, that the contraction is owing, not to the adhesions themselves, but to their slow formation. Now the more slowly these are formed, the less chance will the lung have of expanding. He says that if the effusion be copious, and consequently the resolution of the pleuritis slow, the contraction is evident long before the complete absorption of the fluid; but he says the more rapid the absorption, the less chance is there of contraction, since the longer the lung is compressed, the greater is the loss of its natural elasticity. In short, Laennec himself does allow that the degree of the continuance of the compression through the effusion is the cause of the inability of the lung to recover itself. I myself have continually opened persons in whom the lung has never recovered itself, and yet there have been no fibre-cartilaginous bands and no bloody fluid, so that the long continuance of the compression appeared sufficient to explain

the inability of the lung ever to recover itself.

When the chest contracts in chronic pleuritis, it may begin at an early period of the effusion, but it may not be perceptible for months. Of course it can only be a certain degree of contraction of the chest that is observable, and those persons who are not in the habit of examining patients with the eye and with the hand, who consider those as mechanical means, fit only for the surgeon—those who are not in the habit of making patients undress, and not accustomed to handle them, except to feel the pulse—will of course be ignorant for a great length of time of contraction of the chest. It may be going on for a considerable period, and they may know nothing at all about it till the patient makes the discovery, and announces it to his medical attendant. When the chest is contracted, when fluid no longer exists, but the lung is compressed, and the thorax goes down upon it, then there is a dull sound upon percussion, just as when pleuritis existed; and sometimes you have not only a dull sound, but a true fleshy sound, the same sound as if you struck the shoulder or the thigh. But notwithstanding you have this dull sound, respiratory murmur is heard a little. Probably at the lower part of the chest, where the effusion had taken place first, and must have ceased the last, because of course it is to the lower part of the chest that it will gravitate at first as well as at the last, there will be no respiratory murmur, but it may be heard faintly at the upper part.

When the inflammation has ceased, and the effusion to which the inflammatory state gave rise has ceased, the walls of the chest are flattened down proportionately to the new contracted dimensions of the lung, and nature has effected a cure exactly in the same way that a surgeon effects a cure of hydrocele—by adhesion. In the case of a hydrocele, there is a serous membrane, and when it is inflamed by an injection, fibrin is poured forth, and also serum; the serum is at last absorbed, but the fibrin blocks up the cavity altogether, and that is exactly the state of the parts in the cavity of the chest. When nature has effected a cure in the way that I have now described, the person is more or less deformed for life, but suffers little inconvenience: the general health may be excellent. Laennec mentions the case of a distinguished surgeon at Paris whose chest was contracted after pleuritis, which took place in youth, and in whom percussion, when Laennec wrote, gave a dull sound at the lower and lateral parts of the affected side of the chest, and the respiratory murmur was weaker than on the opposite side; but this surgeon had a strong

voice, and contrived to lecture once, or even twice a-day, for an hour at a time, without any inconvenience.

Treatment.—Besides the surgical treatment of such a case—letting out the fluid—it is necessary to support the strength, and to lessen the irritation by means of opiates—to use the same constitutional means that you would in the case of a large abscess.

Hydrothorax.—It sometimes happens that an effusion of fluid takes place in the pleura without much inflammation. A quantity of serum is effused there, sometimes quite clear, sometimes more or less turbid, and of various characters, but it is not pus, nor is it the result of inflammation. This is commonly called *hydrothorax*. You will recollect that when I spoke of dropsical effusion, I mentioned that effusions in a serous membrane were sometimes puriform, purulent, bloody, and so on; and I mentioned that sometimes they arise from violent inflammation, sometimes from moderate inflammation, sometimes apparently without any inflammation at all. These were general observations. Now the pleura is in the same predicament as all other serous membranes. It is frequently in the state I have now mentioned from inflammation, but sometimes it contains a quantity of thin fluid where there was scarcely any inflammation at all, where there was no necessity to employ antiphlogistic means, and sometimes it contains a large quantity of serum, without our being aware, not only during life, but after death, that inflammation has occurred, in fact, without the least sign of inflammation. Effusion may take place in the pleura, as in other parts, without any signs, just as a person may sweat, and pour forth fluid, without any inflammation whatever.

Idiopathic Hydrothorax a rare occurrence.—But a genuine idiopathic case of hydrothorax—water in the pleura, is a very rare thing. You will hear some people who never examine the chest during life, but open bodies after death, speak of hydrothorax as the most common thing in the world; but when it does not arise from inflammation, hydrothorax is a rare disease. When there is any other disease in the chest, it is common for effusion to take place; but for it to take place, except as a consequence of inflammation, or some organic disease in the chest, is very rare: I do not recollect half a dozen such instances.

Auscultatory Signs.—When, however, hydrothorax occurs, whether it is the result of a very slight kind of inflammation, or is produced by bronchitis, or peripneumonia, or disease of the heart, or any other disease, the symptoms discoverable by the ear are just the same as those that occur when

the fluid is puriform or purulent, and the result of decided inflammation. You have, of course, a dull sound on percussion, from the presence of fluid, and no respiratory murmur at the lower part, although you may still have it at the upper part, (unless the chest be completely filled) below the clavicles, and you have it on each side of the spine where the fluid does not compress the roots of the lungs.

General Symptoms.—The general symptoms are, of course, difficulty of breathing, deficiency of urine, swelling of the legs, cough, a sudden starting from sleep; but all these things, when they do occur with a certain degree of effusion into the chest, are more frequently the result of other diseases in the chest than of hydrothorax. In almost every case you open of hydrothorax, you find other disease sufficient to explain the symptoms. In most cases you find disease of the heart, or chronic disease of the lungs; and in those affections you have exactly the same symptoms, although there be not the same quantity of fluid effused into the pleura. I have over and over again opened patients who have been supposed to die of hydrothorax, whereas death arose from disease of the heart. You will find cases set down as hydrothorax where the legs are swelled, the breathing so difficult that the patient is unable to lie down, and he has orthopnea and deficiency of urine, and there is a collection of symptoms which are pronounced to be hydrothorax; whereas, if you listen to the chest, you hear respiration all over it, and if you strike the chest you hear the usual sound; but on listening to the heart you hear disease of that organ, or on listening over the chest you find sonorous and sibilous rattle, shewing that there are other diseases present. The fluid that occurs in the chest, when it is not puriform, is usually the result of some other disease in the chest. In cases of effusion into the chest, under all circumstances, you have the same auscultatory phenomena; not only the want of a respiratory murmur, not only the want of a hollow sound on percussion, but if the fluid be not considerable you have ægophony. No matter what the disease is, the phenomena are the same.

Treatment.—Now if you can ascertain that there is really hydrothorax to an amount sufficient to explain the symptoms, that there is a dull sound all over the chest on percussion, that the respiratory murmur is not heard any where except just below the clavicle, and at the root of the lungs, and you see the general signs of dropsy, and the absence of disease of the heart, you then may presume that the extreme difficulty of breathing, the swelling of the legs, and the scantiness of the urine, arises from

a collection of fluid in the chest, especially if you hear œgophony, and observe that the dulness of sound and want of respiratory murmur increase, reaching higher and higher, and in such a case you ought to let out the fluid. Exactly as in other cases, where the presence of a collection is doubtful, you may use the needle which I spoke of in the last lecture to ascertain whether fluid exists there or not. It would be well to do it in every case, because it gives no pain to the patient, and is perfectly safe.

But before these measures are taken, it would be right to give the common remedies for dropsy where there is no inflammation—to give diuretics. Digitalis answers an excellent purpose, and also squills, more especially if united with a small quantity of mercury, which appears to increase the diuretic effect. You may do a great deal of good by these remedies in all cases of chronic difficulty of breathing, whether there is effusion of serum or not, because there is continually a great collection in the air cells, and perhaps also in the cellular membrane of the lung, which impedes respiration. When there is not hydrothorax, properly speaking, you continually find that diuretics are very useful, by causing an absorption of the fluid which is pressing the cellular membrane of the lungs, or filling the air-cells themselves. I mentioned when speaking of dropsy before, that diuretics answer more purposes than one.

unfettered liberty of expansion; and we find the cavity in which they are contained surrounded by firm but moveable parietes, themselves the agents of the movements they allow. The third cavity is the ABDOMEN, not only fitted by its mechanical structure for the reception and protection of a complicated collection of organs, but so made up of tissues, at once firm yet moveable; soft and yielding, but elastic, as to admit without injury of the constant movements of some of its contents, and the variations in dimensions to which almost all of them are subject, either during the natural but irregular periods of their own activity and rest, and still more violent changes in disease, or during the operations, both healthy and deranged, of neighbouring organs.

It is on this third district of the body that I now wish to fix your minds; and it is my intention—at the risk of being prolix in some parts and superficial in others, and with the certainty that what I am about to say will be known to almost all my hearers—a sad but necessary conviction in an assembly like that which I am now addressing—it is my intention, in the first place, to detain you a few minutes while I briefly state the extent and boundaries of that large region of the body to which I shall have occasion during this and two following lectures somewhat irregularly to direct your attention. I shall, then, shortly state the outline of those important functions which are ever unconsciously proceeding within its limits, and at the same time glance rapidly at those structures, on the integrity of which the various functions must depend; I shall then call to your mind some of the deranging causes from which disease arises; and, finally, do what in me lies to compress within the short space allotted me, the principal features by which we must seek to distinguish some of the most striking diseases; without attempting to fill up an outline whose faintest markings will excite in your experienced minds far more important views than I should be able to suggest, however prolonged my discourse.

First, then, as to the boundaries of the region which I intend to include under the appellation of the abdomen. Above, it is separated from the chest by the diaphragm; below, it is supported by the pelvis; behind, the dorsal and lumbar portions of the vertebral column, and the masses of the dorsal and lumbar muscles, form its boundary, and the basis of attachment for various organs which it contains; on the sides, the ribs and the transverse muscles; in the front, the straight muscles of the abdomen, with the tissues of the common integuments, limit its contents. Thus, in the extended view which I propose to take,

GULSTONIAN LECTURES, 1833.

ON THE

FUNCTIONS OF THE ABDOMEN,

AND SOME OF THE

Diagnostic Marks of its Disease.

BY RICHARD BRIGHT, M.D. F.R.S. &c.

WHEN we turn our attention in the most general manner to the structure of the human frame, one obvious division of its various organs immediately suggests itself. We see the cavity of the skull, and of the spinal column, forming a secure and firm receptacle for those important parts which, by the delicacy of their functions, and the tenderness of their structure, need all the protection which a mechanism at once solid and capable of much motion is so well calculated to afford. We see, secondly, the frame-work of the chest, protecting parts as essential to life, but whose functions altogether depend on a free power of extensive motion, and an almost

the kidneys and the pelvic viscera will fall under consideration; and to this I am led because they are too closely connected in situation, and too intimately allied in function, to be advantageously separated from the viscera of the abdomen.

We find included within this space tissues of every structure, and functions the most various—an ever active laboratory, where multiplied operations are carried on, of which, after all our research, we often know little but the results, incapable as we are of following out the chemistry of nature, and generally but little skilful in comprehending even the grosser parts of the apparatus she employs.

What, then, let us in the first place inquire, is the general character of these operations? They are operations of digestion—of assimilation—of absorption—of secretion—and of excretion,—in which we have much and continued involuntary motion, and much varied circulation; to effect all which there is need of a large supply of that peculiar modification of nervous power which is termed involuntary, which depends upon the ganglionic system, while all is supported, nourished, and stimulated, by a curious and variously distributed vascular apparatus.

First amongst these operations I would place digestion. In order to afford the most suitable supply and stimulus to the stomach, saccharine, albuminous, and oily substances, should, we are led to believe, be mingled with each other, and presented to the stomach in a moderate state of firmness; neither very hard, nor, on the other hand, in the fluid form. When the stomach receives them, it is excited to action, a peculiar secretion is thrown out, and by an influence which is the result of combined chemical, mechanical, and vital action, those parts of the mass which come in contact with the surface of the stomach undergo a peculiar change, and are gradually urged on towards the pylorus. What the precise changes are which take place in the stomach, has been matter of much investigation, but the result is not sufficiently definite to be satisfactory. The whole mass is more completely comminuted, and is rendered acid; and it is stated, as the result of microscopic observations (doubtful evidence, I own), that globules are here generated, white, but bearing resemblance to the red globules of the blood; and it would appear that the more fluid parts are absorbed, probably through the veins. As the chyme passes gradually from the stomach, the next four inches of its course are the seat of very active and important operations. The duodenum is not only provided with secreting apparatus in its own structure, but receives very important contributions from the two large and

remarkable viscera, the liver and the pancreas, over whose excretory ducts, and over the activity of whose secretions, it probably exerts great influence mechanically, by its alternate dilatation and contraction, and likewise through the medium of nervous connexion.

In the duodenum, albumen makes its appearance to a much greater extent than it did in the stomach, probably in part from the addition of the pancreatic fluid. The nutritious and feculent parts are separated; and it is stated that globules of an organic nature are here much more distinctly traced than in the stomach. Nothing can be more aptly contrived for the purpose of agitating, mixing, and presenting every portion of the alimentary mass to the surface, by which certain parts are to be absorbed, than is the whole structure of the small intestines. Its muscular fibres, formed for producing a constant undulatory vermicular motion, and loosely lined by the absorbing membrane, whose numerous plicæ and valves are affording a very wide surface, as they stand protruded, with their villi erected, and, as it were, intimately mixed with the semifluid substance into which the food has been reduced; while the external surface is covered with a polished and constantly lubricated surface, greatly facilitating the motion of the various parts upon each other.

In this lengthened passage, and the long exposure to the animal temperature, some sensible chemical changes result; but probably something far more important, though less intelligible, has been going on, and the mass, which had, previously to its being selected as food, undergone the first changes of organization, is now in some degree assimilated to living animal matter; for though there is no proof of the exact situation in which this curious change commences, there is reason to believe that, from the moment the morsel enters the lips, it is more or less subjected to the influence of those nervous and living actions whose effects are recognized as more fully developed in the perfect blood. Digestion and intestinal assimilation are not completed throughout the whole of the alimentary matter, even in the small intestines, but appear to be still proceeding in the cæcum, where very sensible changes shew themselves in the faecal mass, which then, advancing by a slower motion, and under circumstances of greater pressure, is transmitted forward to the colon and the rectum.

Another process carried on within the abdominal cavity is absorption. This indispensable function is ever most actively proceeding from each interstice of that region now under consideration, as it is from

every other part of the body; but it is here effected in a still more direct and appreciable manner, from the extensive cavities lined by serous, and the hollow viscera lined by the combined mucous and villous membranes; for besides the absorption of solid parts, necessary in the perpetual process of their change, we here have the daily and hourly absorption of nutritious particles from the food, and the unceasing absorption of that serous fluid which, once secreted, and exhaled in the attenuated form of vapour, is again to be received, probably endowed with fresh properties, into the circulating fluid; and should these processes of absorption fail, the body must in one case sink, worn out by inanition; or, in another case, must die oppressed by the increasing accumulation of fluid, not only mechanically impeding the operations of the abdomen itself, but fatally interfering with the functions of respiration and circulation.

What the means by which these processes are carried on, the scalpel and the microscope have as yet but imperfectly informed us; but while we recognize, and can trace, a peculiar set of vessels loaded with the milky particles of chyle, and the more pellucid fluid from the cavities, and from the interstices, bearing their contributions through the absorbent glands towards the heart, we have reason to believe that the veins themselves admit of absorption in a more direct manner through their coats; thus doubtless affording pabulum to the blood of different qualities, and differently prepared, and probably intended, as in the case of the double organs of the body, to furnish a vicarious assistance in the essential process of nutrition, when disease has partially impeded the course of the lymphatic vessels.

The abdomen, likewise, contains by far the greater number of the secreting and excreting organs, in many of which there is obviously to be traced peculiar arrangements of parts, which we cannot doubt to be instrumental in the separation of the respective secretions, although we are quite unable to point at the mode in which the structure promotes the object to be effected. Whether it be by the minute separation, by the mechanical delay, or by the relative position into which particles are brought, favouring some process of attraction, we may conjecture, but as yet are not in a situation to assert. It is impossible to turn the attention to the complicated, almost confused, and massive structure of the liver—the comparatively obvious disposition of the kidney—the more apparently simple arrangement of the pancreas—the extensive and dilated apparatus for secreting mucus—the simple

diaphanous membrane which pours forth the serum—and not to feel convinced that much of these varied powers depend in some way upon their organic arrangement, although there is no obvious connexion between any of these arrangements and the effects produced.

Amongst these secreting organs the liver is one of the most striking, occupying a large space in the right hypochondriac region, where it fills the concavity of the diaphragm, partaking in some degree of the motions of that muscle; and besides being, like other parts of the body, supplied with arteries, it has a large quantity of venous blood constantly poured into it by the vena portæ, which is formed by the junction of several of the abdominal veins, and ramifies like an artery in the substance of the organ. Thus it has two sets of vessels going into it. It has also two sets coming out: one, the vessels forming the hepatic vein; the other, the biliary ducts uniting together to form the hepatic duct. The two sets of vessels going in, carry, one arterial blood, the other blood bearing the venous character. The two sets of vessels coming out, carry, the one venous blood, the other bile. In addition to all this apparatus, absorbents are distributed abundantly both to the surface and to the substance of the liver, and nerves from the hepatic plexus are insinuated into every part. Besides all these vessels and nerves, the liver has a structure, composed of a granulated substance, which seems made up of convolutions, between which vessels are seen ramifying; the hepatic vein, adhering, as we are told, closely to the granular structure, and the fine branches of the hepatic artery and the vena portæ distributed in the cellular membrane filling the interstices, and the fine terminations of the biliary ducts said to communicate with both these sets of vessels. Still, however, it must be confessed that few problems in the anatomy of structure are more difficult to solve than the structure of the liver, and it is by no means certain from which set of vessels the bile is derived. It has usually been believed that it was furnished by the blood of the vena portæ, but this has been doubted; and some imagine, as I have just stated, that both the arterial blood and the blood of the vena portæ are concerned in furnishing the secretion of the liver. Be this as it may however, the blood which has gone into the organ returns very like other venous blood, but to become so has furnished a large quantity of that fluid which fills the biliary ducts, namely, bile, and has consequently undergone great change or purification; and this is probably one of the very important offices which the liver

has to perform; but in doing this, those elements which have been withdrawn from the blood as injurious to it, are formed into a most useful compound, flowing in part along the hepatic and common duct into the duodenum, and in part drawn in by the cystic duct into the gall-bladder. The bile, which flows at once into the duodenum, without going to the gall bladder, is of a more bland and milder character than that which remains for some time in the gall-bladder, where it acquires a dark colour, a viscid consistence, and a bitter taste. In what respects these two different species of bile, if I may so call them, act differently from each other in the intestines, is not known, but in all probability they have, to a certain degree, different functions to perform. One fact, however, is known—that if the bile be prevented from flowing from the common duct into the duodenum, healthy chyle is not formed; and if the bile is forced to mingle with the circulating mass, the whole system suffers.

Scarcely inferior to the liver, in whatever point of view we consider them, are the kidneys, which, lodged in a secure recess in the loins, are ever proceeding with their curious labour of analysis, extracting, by means which to outward appearance seem most inadequate, a host of saline ingredients from the blood: nor, looking at the character and variety of the secretion, can we wonder that should this fabric be interrupted in its operations, most direful consequences should ensue, every successive stroke of the heart propelling a poisoned stream into the veins, unfitted for healthy nutrition, or for affording the proper stimulus to the various secreting organs.

Next, the pancreas, a gland whose powers are probably as yet but ill appreciated, whose secretion performs an important part in the process of digestion, and which is placed in a position at once most singularly secure from external force, and most aptly chosen to expose it to the pressure and irritation of the stomach and duodenum at times when their active operation stands in need of its assistance and support.

No organ of the abdomen has excited more doubt as to its function than the spleen; and without entering into the various conjectures which have been advanced, I shall be content to adopt the opinion of those who consider it as not improbable that one at least of its duties is to serve as a kind of safety-valve, or reservoir, where a certain portion of blood may be held back when not needed, and from which it may be returned to the abdominal circulation according as more or less is required during the temporary

and changing periods of activity and rest in the various organs.

Nor let us in this enumeration pass by unobserved the functions of the serous membranes; let us not mistake their office in the system, nor be content to believe that nature has formed this powerful, this ever-labouring structure, whose vessels appear capable at all times of secreting so abundantly, and which under disease pour forth an overwhelming quantity of serous fluid,—let us not hastily infer that nature has worked out this secretion for the sole purpose of lubricating surfaces, and rendering the motions of different parts mechanically free and unimpeded. There is no reason to doubt that a fluid thus largely formed, thus constantly taken back into the system, affords a necessary supply of vitalized support to the blood, and therefore, when secreted, it is not allowed to escape.

Nor by parity of induction can we easily overlook the united secreting and excreting functions of the powerful mucous apparatus distributed thickly beneath certain absorbing surfaces; nor can we deny the probability that a compound thus ejected from the system is possessed of qualities, or composed of ingredients, which would in some way act injuriously if retained.

The great object of much of this skilful structure and these complex operations is, the preparation of the blood for stimulating the nerves and nourishing the body, to which end all the functions of the abdomen, except those which belong to the preservation of the species in some way, tend. When we speak of nourishing the body, we are too apt to consider the stomach as the alembic into which, the food being placed, the pabulum of life is at once concocted; but when we reflect a while, we soon perceive that the stomach is little more than the living vestibule of one grand department of that busy laboratory where numerous processes are going forwards, each under the direction of its own Archæus, who arranges and builds up his apparatus, and selects his ingredients, so that he may bring out his own results with the least possible interference in the operations of his fellow workmen, each adding something useful, or eliminating something baneful, till the complex process is completed. Nor are these thrifty workmen prodigal even of what they reject, but ever turn it to some good account, devoting it at once to some useful purpose, or storing up the surplus quantity till a time when it is more needed; for in this point of view it is well worthy of observation that the various processes of excretion, while they carry off from the blood substances which would prove most injurious to the

body, are generally devoted to some such definite useful purpose that it is difficult to say whether the mischief which is averted, or the good which is effected, is the most important result of the operation.

Not only is the poison which is drawn from the blood in the form of bile so essential to the work of digestion that it might safely admit of dispute whether that were not the first and most indispensable object in its excretion, but it likewise, in its passage from the body, affords the most suitable stimulus to the intestine to rid itself of the excrementitious portion of the food, while it moves the whole forwards, to present it to the action of the absorbents.—The large quantity of mucus excreted, no doubt for wise purposes, from the blood by certain membranes, lubricates their surface, and protects them from the action both of the air and of those various substances which themselves stimulate the secretion.—The tear not only protects the eye, but moistens the membrane of the nose, keeping it in a state fitted to receive the impression of objects of smell.—The saliva, ere it mingles with the food, preserves the organ of taste in a state to be acted upon by its proper stimuli.—The deadly urine, both when retained within the bladder, and at the moment of its expulsion, appears to act a very important part, constantly maintaining, by the stimulus it affords, the muscular apparatus in a condition to perform its occasional office, and keeping up a proper stimulus in the canal of the urethra, which probably conduces greatly to the regulation of the sexual inclination, for we find that sometimes, when it loses its natural properties, as in diabetes, the passions are insufficient alone to promote the desire, while in other cases the diseased urine affords unhealthy and excessive stimulus to the parts.

Thus we see, and the more we examine the more we see, the beautiful economy which presides over all the arrangements of the system, whose delicate and varied operations are ever returning on each other, seeming to render almost unexpected assistance in their mutual and united tasks.

It is necessary that all these processes, and others not taking place within the abdomen, should be perfectly performed, in order that the most completely healthy condition of blood should be obtained; but it is not to be doubted that considerable imperfections may exist, and even continue for a long period, in some of them, without much essential, or at least much obvious derangement being induced. Within certain limits the functions have the power of recovering their natural action even by the spontaneous efforts of the system, but beyond those limits mischief

proceeds with accelerated step, each imperfection giving rise to others, till the whole fluid, together with the apparatus in which it is prepared, is involved in one common ruin.

To explain the way in which each individual process influences the blood, and point out the different shades of mischief consequent upon each deviation from the healthy action of every organ, would, in the present state of our knowledge, be impossible, and is scarcely, indeed, within the scope of rational expectation; but still were it not that we have learnt from long experience to acknowledge the difficulty of investigating processes in which vital action is concerned, we should be inclined to express surprise that we had made so little progress in tracing great and almost visible alterations, apparently connected with derangements, which are little short of being tangible in some of the most important of the viscera.

Some few facts, however, seem to be ascertained: thus, for instance, we know that if the bile be not fairly carried from the circulation, consequences the most decided will result, and gradually the poisonous material, branded by its colour, will be traced in every vessel—will tinge every structure—will infuse itself into every fluid, and influence almost every action of the system, inducing formidable disease, till, ere long, the powers of life become exhausted and the body sinks, oppressed by the deleterious influence of the imperfect blood.—We know, by much more recent observation, that when the kidneys perform but insufficiently their office of depuration, the whole frame quickly feels the shock; and if the deranged action continue long, the urea can be detected by the chemist's art, in the course of circulation. The body becomes enervated; the mind loses its elasticity; and a decay, marked by anasarca, or a more sudden death, from attacks upon the nervous system, or from the supervention of uncontrollable inflammation, sooner or later closes the scene.—We likewise collect from observation, that when the fluid parts of the blood are too profusely thrown off, as in cholera, or as when a great and unnatural exhalation takes place into the serous cavities, the blood either rapidly shews it, by its diminished fluidity, or the body wastes slowly, from want of a due supply of natural blood; or when, as in anasarca, the abundant serous secretion seems attended with a somewhat proportionate absorption, we find the watery portions of the blood increased and the natural qualities of the fluid destroyed.—When the supply of nutritious particles is early cut off by obstructed lacteals, or by the undue hastening of the food

through the intestines, the blood is also circulated in an impoverished state; and many circumstances of external agency, acting probably through the nervous system, have been found to bring that fluid into the weak unhealthy state which marks the patient as the subject of anæmia, or chlorosis.—Should the nourishment be of an unwholesome quality, or notably deficient in quantity, we shall, under certain combinations of circumstances, find the crasis of the blood diminished, and that hæmorrhagic tendency engendered which forms so prominent a feature in the scurvy.

A few, then, of such general facts are known, and valuable they are, as hints and assistances in practice and in the further pursuit of our observations: but even for these few we are greatly indebted to very modern investigation,—and we have reason to hope that the intelligence and zeal which are now more than ever directed to the investigation of the chemical phenomena attendant on the natural processes and the diseased actions of the body, coupled with the minute and ardent pursuit of pathological anatomy, will gradually lead to results still more widely extending our views, and leading us still more closely to follow in the path which nature points; gradually, I say, because, to be of real benefit, all researches of this kind must be grounded in patient perseverance in the observation of facts, the comparison of results, and the repeated verification of experiments; and let it not for a moment be supposed that I so far credit the chemist's art, or the pathologist's skill, as to believe that their united sciences will be able to guide us through the intricacies of disease; there are yet things invisible, untangible, in our frame; there is yet vitality; there is yet the nervous influence. If the eastern blast can in an hour change the properties of the blood—if the electric influence can, in the twinkling of an eye, deprive that fluid of the power of coagulation—if the vessels of the conjunctiva may in an instant, through the effects of atmospheric exposure, be paralyzed, and suffer the blood almost to stagnate in its course—if the insensible emanations from marshy land can, in a few minutes, pervert the natural actions of the whole system—if sudden grief annihilates the appetite, or the very thought of a disagreeable or disgusting object reverses the muscular action of the stomach—are we not to look for something beyond chemistry, something beyond the demonstrations of the pathologist, to instruct us in health, to guide us in disease? Yes, there is a nervous system, whose fine cords we trace in their almost infinite subdivision, whose functions we can often ascertain; and many a remedy which the

experienced practitioner administers, because experience has taught him its efficacy, and which the chemist or pathologist may give grudgingly, because he sees not why it should be efficacious, acts through the medium of an unseen chain, now influencing the involuntary actions through the intervention of the ganglionic system, now exciting the sentient and now the voluntary powers; and perhaps not seldom acting though the still more subtle, but not less positively existing, influence of the mind.

The great object for which the blood is prepared is the maintenance of the body, both by the stimulus it affords the nervous system and by the process of nutrition; in which, as in other processes of the animal economy, we are obliged from the results to infer the action; for no more in this than in the case of secretion (of which it may even be considered but a modification), are we able by our senses to detect the progress of the work. Innumerable are the points in which matter is constantly deposited, and very various the materials thus unceasingly contributed towards the building up and the repairing of the frame. There can be little doubt that the vessels and the nerves are the immediate cause of all this varied effect; and from the constancy with which we observe peculiar modifications of matter supplied to particular parts, we are apt to infer that there is some peculiarity in the structure, the subdivisions, or the minute distribution of the nerves and blood vessels, rendering them fitted for producing certain effects in certain parts: and yet, after all, this is but an assumption; for the growth and renovation of parts may be but the result of partial attraction or polarization, by which the blood is made to deposit certain particles in certain localities, and in apposition to certain similar substances, while the blood-vessels and nerves may be performing but general and uniform functions, as the carriers of blood and the promoters of action in all the different and varied structures.

Such being the rude outline of the functions performed by the diversified structures contained within the limits of the abdomen, having for their ultimate object the formation of the blood and the healthful stimulus and nourishment of the body, we have still another set of organs—the uterus and its appendages—which adds largely to the list of abdominal diseases in the female. This organ is one of the most important in the system. Its functions are so peculiar, so different in every way from the functions of any other organ, that they are exposed to constant sources of derangement; and its sympathies with other parts of the body are so extensive, that

when derangements occur they shew themselves by connected derangements in almost every organ. In this point of view, therefore, in reference to its sympathies, it becomes absolutely necessary that we should bear in mind many of its derangements, when occupied on the general subject of abdominal disease: and, moreover, many most important points of diagnosis are involved in a consideration of those tumors which depend upon affections of the uterus itself, and diseases of the ovaries and other appendages.

[*To be continued.*]

OBSERVATIONS

ON THE

STRUCTURE OF THE PLACENTA.

By HUGH LEE, M.D.

Physician Accoucheur to the Middlesex and the Westminster General Lying-in Hospitals.

THE recent death, in the ninth month of gestation, of one of the nurses of the Middlesex Hospital, having afforded me a favourable opportunity of examining the structure of the placenta, and its relation to the uterus, it has been suggested to me, that a detail of the results of my observations and inquiries might be at the present moment not altogether devoid of interest. The subject is one confessedly of great intricacy, and peremptorily demands that combination of "accuracy of observation with fidelity of narration," from the want of which Dr. W. Hunter was wont to allege in his lectures, that "all our great men lie like the devil." It will be my purpose therefore, in the ensuing paper, to deal rather with facts than impressions—to dwell rather upon what I saw than upon what I may have thought; and I shall, as far as the nature of the inquiry will allow, studiously abstain from cavilling at, or even canvassing, the opinions of others.

This poor woman died almost suddenly, from disease of the heart; and as there had been no symptoms actual or preliminary of labour, the connexion of the placenta with its containing organ was undisturbed even by the contraction of the uterine fibres. The gravid uterus with its contents having been removed, for the purpose of examination, to the hospital, which was contiguous to her residence, the uterine vessels were first effectually cleansed of any blood which they might contain, by the injection

into the right spermatic artery of a considerable quantity of warm water. Through the same vessel my friend and former pupil, Mr. Beevor, of Berners-street, then injected double size, coloured with vermilion, until no more would pass without the employment of such force as might endanger the occurrence of laceration and extravasation, which we were most solicitous to prevent. The pipe of the injecting syringe was then introduced into the artery on the left side, which would, however, only admit a small quantity, not exceeding one-eighth of what had passed by the first injection.

The uterus was now cut open, for the purpose of removing the child, for which the friends were waiting, that it might be buried with the corpse of the mother, when in its divided edges could be distinctly seen large veins traversing the parietes. Though not greatly distended, they were still abundantly conspicuous, and from their canals, even by very moderate pressure, could be squeezed out separate portions of injection.

Upon inspection of the fetal surface of the placenta, whilst it remained attached to the uterus, it appeared even through the membranes to be uniformly red. The whole mass presented its usual external characters. The flat empty white vessels were ramifying under the membranous expansion, but the entire surface preserved its regularity of form; it was neither more elevated nor more depressed at any one part than when, recently expelled from the uterine cavity by living efforts, it contains only blood. A portion of the membranes of the ovum being peeled off, the appearance underneath very closely resembled that of the surface by which the placenta is attached to the uterus. A distinct layer of decidua, manifestly thicker at the edge than elsewhere, was continued over this aspect of the placenta. It differed in nothing but its thickness from the same membranous substance upon the uterine surface; of this, indeed, it was obviously a continuation, and afforded the most unequivocal evidence of the accuracy of Dr. W. Hunter, and more especially of his editor, Dr. Baillie, who has thus minutely described it:—"The layer of the decidua which lies between the chorion and the placenta, is in one case much thicker than another; it sometimes forms a smooth, tender, opaque mem-

brane, but is more frequently reticulated, especially towards the edges of the placenta, looking somewhat like lace." This reticulated character was rendered beautifully manifest by the distinctness with which the small masses of red injection could be seen through this portion of decidua. The nodules were minutely subdivided, and varied both in their magnitude and their direction. Some appeared not larger than corn, or canary seeds; others were nearly as large as grains of wheat, with a form also regularly defined, and much resembling the latter of these grains, being oblong, with rounded narrow extremities. In their direction too they differed somewhat. In general they had no determinate arrangement, but in some instances they seemed to have a linear distribution, conveying the idea to some who saw them that they might be vessels. These small masses were intersected by colourless semi-transparent lines, which defined their form, limited their extent, and conveyed to my mind the impression that they were membranous septa; and whilst they had no remote resemblance to the cut surface of the interior of an orange, they amply verified Dr. Baillie's description of a "*reticulated*" and "*lace-like*" appearance. But though the substance of the placenta was thus minutely injected, its fetal surface was uniformly smooth and concave; no where could be seen large and irregular masses such as extravasation would produce; at no one point, either of its surface or its very edge, to which the injection had equally penetrated, did it appear to be broken down upon the one hand, or elevated and distended upon the other, to the extent of producing the slightest irregularity.

By a force not exceeding, if even equal to, the weight of the placenta, and avoiding all pressure upon its substance, a portion of the edge, equal to about three inches in one direction, by more than an inch in another, was then separated from its attachment to the uterus. This brought into view those small but "very numerous" blood-vessels, described by all who have had opportunities of investigating this subject, and varying in size from mere filaments to the diameter of a crow quill. These, as the separation proceeded, were seen to be elongated to the extent of nearly half an inch before they were torn by the force employed, and stretching across

the angle formed by the already separated surfaces of the placenta and uterus. They generally gave way at their point of attachment to the tender decidua upon the surface of the placenta, and their remaining portions receded, apparently by their own elasticity, to such an extent that it was difficult, and in the majority of instances impossible, afterwards to trace their orifices. It must be obvious, however, that if these vessels were torn, or if they had been cut, as they were in a case recently examined by Mr. Owen, to prevent the effects of violence, such orifices must of necessity exist, though they may be in many instances invisible, from the torn or cut vessels retiring completely within the substance of that irregular layer of spongy and lamellated decidua which remains attached to the uterus.

Through the smoother decidua upon this detached surface of the placenta, as upon the fetal aspect, could be seen its interior equally and uniformly injected. As, however, here the membrane was thicker and more compact than the decidua immediately beneath the chorion, the precise arrangement of the portions of red injection was less manifest. But in an investigation of this kind, upon which there has been much of controversy, negative facts are by no means unimportant; and it would therefore be improper to omit the observation, in which all who were present and minutely examined the parts concurred, that there were no large irregular masses or layers of injection between the placenta and the uterus, and not the slightest appearance cognizable to the senses of either laceration or extravasation. The only portions of disentangled injection which came into view, we saw escaping, as pressure was applied to the parietes of the uterus, from those large openings upon the interior of the uterine cavity, known to most of the anatomists of the middle of the last century, and very particularly adverted to by my friend, Dr. Robert Lee, in his communication to the Royal Society. These apertures could be distinctly traced by the introduction of a probe, though they were partially, and in many instances almost entirely, covered by that portion of deciduous membrane which, still attached to the surface of the uterus, presented a lamellated character easily separable into layers, and led obliquely to the openings, which, in conformity

with the opinion of the Hunters, I am inclined to consider rather as the extremities of the uterine veins than holes in their sides, as would appear to have been the notion of the two professors, "*primus et secundus*," Monro, of Wallace Johnson, and possibly, though far from certainly, of Dr. Robert Lee; or than "cæcal appendices" to the veins, as they were believed to be by Astruc.

Having thus acquired as much information as it appeared probable we should obtain from mere inspection of the placenta, which had been hitherto only injected from the spermatie arteries of the mother, it was determined to inject next the vessels of the umbilical cord, for which purpose I returned to the hospital at the expiration of a few hours. In the interval, however, some one had carelessly or mischievously separated the whole placenta from the uterus, and in doing so had produced a longitudinal fissure upon its uterine surface of about two inches in length. On the most minute examination, however, of this rent, we could detect no large deposit of coloured size near the part, nor upon the corresponding surface of the uterus, nor in the flat vessel which contained them both; nor was there an approach even to evidence, or any thing to lead to the suspicion that it was produced by the force of the injection; on the contrary, it was the opinion of all present, some of whom were more conversant with anatomical inquiries than myself, that the laceration was, beyond all doubt or question, the result of rough handling subsequently to the first injection. Nor can I refrain, though I do it with great deference to the opinion of others, that in the case described by Dr. Donald Monro there was any thing like convincing proof that the injection of the placenta was the result of either laceration or extravasation. That there was a layer of injection between the uterus and the placenta, is unquestionable; but the description of the appearance leads me irresistibly to the conclusion, that the placenta had been filled before this layer was thus deposited, and that it was thrust out of the sinuses by the subsequent injection upon the second day; which was the explanation offered of the fact by his brother, Dr. Alexander Monro.

The uterine surface thus detached from the uterus, exhibited its lobules, with their intersecting sulci, even more

distinctly than they are seen in the uninjected placenta; and in several parts could be perceived, with the naked eye, small apertures of an oval form, with edges perfectly smooth, regularly defined, and thicker as well as more opaque than the contiguous parts of the decidua which they penetrated. They varied somewhat in their size, and in more than one instance appeared arranged in pairs, at the distance of less than half an inch from each other. They seemed to have membranous continuations of a tubular character, into which a round-headed probe dropped, almost by its own weight, nearly to the opposite or fetal surface of the placenta. These apertures much resembled others which may always be detected in considerable number passing through that portion of the deciduous membrane which, like the pia mater amongst the convolutions of the brain, dips into the sulci which separate the lobules, and which openings only require the placenta to be placed in the same convex position which it occupies in the uterus, to make them manifest even to the most sceptical.

The pipe of a syringe was now placed in one of the arteries of the cord, and by very moderate force a yellow injection was thrown in, until it was seen to return by the umbilical vein, the celerity of the passage of the injection, and consequently its force, being, by the resistance arising from the pressure which the weight of the placenta produced upon the trunks of the fetal vessels, placed downwards, that we might see the progress and effect of the injection upon the uterine surface. As the vascular part of the placenta became filled, the lobules with their sulci, which always pass obliquely towards the interior, became even more conspicuous than before, in consequence of the moderate and uniform elevation of the centre of each of these natural subdivisions of the placenta. There was no regular diffusion of the yellow matter under the decidua; but the successive appearance of yellow spots near to the surface at length gave a tint to the whole, the yellow gradually intermingling with the uniform redness previously observed. This tint was more particularly observable towards the centre of each lobule; and at many points near to the surface there manifested itself a most beautiful arborescent appearance, from exceedingly

minute vessels, as the injection was passing through their canals. Through the lacerated portion, and there only, the injection escaped in great quantity, oozing largely from the small vessels, and spirting from the larger like blood from an artery divided in the living body during an operation. But since, as I have before taken occasion to state, none of the red injection was hanging about, or had been apparently forced into the rent, so now none of the same injection could be recognized, either forced before, or intermingled with, the yellow fluid as it escaped from the torn vessels, thus affording the strongest collateral evidence that the laceration was not the result of the force of the first injection through the vessels of the uterus. Now also, upon examination of the apertures already described as penetrating the decidua, they, like the lobules and sulci, were even still more distinct than before, and their membranous continuations, somewhat funnel-shaped, passing towards the fetal aspect of the placenta, became well marked and indisputable. Whatever may be the nature and office of these openings, of which probably the state of our knowledge will not allow us to speak with confidence, at least the apertures themselves were obvious to the unaided senses; and I am happy to have the opportunity of appealing, in corroboration of the accuracy of my description, to Dr. Granville, who is in possession of a portion of the placenta which contained two of the most distinct of them; to my friend and colleague, Mr. Arnott; and to Messrs. Corfe, Beevor, and Elwyn, all of whom saw them, and expressed in the strongest terms their opinions that they were natural openings, rather than the results of laceration, to which they bore not the most remote resemblance. My impression with regard to them was, that they were probably connected with the return of blood from the interstitial substance of the placenta, for which office they appeared admirably adapted.

The placenta was now left till the following day, that the cooling and consolidation of the size injection might be perfected; when, upon inspection of the fetal surface, was seen the beautiful ramification of the trunks of the umbilical vessels before they plunge, in the form of large tubes, into its substance; and it was interesting to ob-

serve the exact correspondence which each large trunk, or congeries of large vessels (for occasionally there was more than one), bore to the lobule or natural subdivision of the placenta opposite to its entrance, which was always nearly in the centre of each globule. This arrangement of vessels very closely resembles that which we find in the human kidney, in which organ each branch of the renal artery, which divides before its perfect entrance, is distributed upon a lobule or natural subdivision which constitutes a distinct secreting organ. This arrangement of vessels also strongly favours the notion, evidently gaining ground both in this country and upon the continent, of the close analogy betwixt the cotyledons of the brute creation and the lobules of the human placenta. This peculiar distribution is beautifully shewn in a successfully macerated placenta which Dr. Granville did me the favour to shew me, and in which each of these main trunks is seen to ramify towards its summit with extraordinary minuteness, so as to be gathered into as many distinct bundles as it may be fairly inferred there must have been lobules, and looking, when the membranes which they pierced were rendered convex by allowing them to hang over the hand, like so many gooseberry or currant bushes in a garden, or (as Dr. Granville expressed himself) like so many stunted oaks in an old forest. The intervening membranous surface was perfectly bald, and, occupying a very considerable space, led to the irresistible inference that whilst the blood-vessels remained, a large quantity of interstitial substance, equal nearly, if not quite, to half of what was required to make up the bulk of the placenta, had been removed by maceration, as well as both surfaces of the decidua.

Having cut through the substance of the placenta from its fetal to its uterine surface, and in a direction parallel to the course of its large vessels before they enter, the two injections appeared much intermingled, though the red predominated towards the uterine, the yellow towards the fetal aspect. This is in exact conformity with what Dr. Wm. Hunter had observed, who referred it to the displacement of the first by the second injection. Both being rendered fluid, from the whole mass being surrounded with warm water, to favour the

passage of the substance injected, the gradual filling of the vessels of the funis pushed the injection previously introduced towards the opposite or uterine aspect, exercising, in short, an influence analogous to that by which it was believed, by John Hunter, that the blood which had done its office in the cellular part of the placenta, was returned into the venous orifices upon the interior of the uterus; the turgidity of the placenta assisting "to squeeze the blood into the mouths of the veins of the uterus, that it may again pass into the common circulation of the mother*." Still, however, the red injection evidently and largely preponderated in the textures immediately connected with the decidua upon both surfaces of the placenta. These, even now, appear almost uniformly red, the decidua having indisputably received its injection from the uterine vessels, from which all agree that, at least for the purpose of nourishment, this membrane receives its supply of blood.

Of the interior structure little could be made out without the aid of glasses of magnifying power. With lenses of moderate power I then examined small detached portions of the placenta, my attention being first directed to the red injection. This appeared to be minutely subdivided into small masses or nodules, which, although the whole cut edge was rendered slightly convex by pressure upon the two surfaces, still retained the position which they occupied, notwithstanding the compression to which the whole portion was subjected whilst held with the fingers, or with forceps, that a strong light might be directed upon it. Nor can I here refrain from noticing the striking contrast between the effects of compression respectively upon the uterine sinuses and the interior of the placenta. The pressure from the fingers and thumb, in simply holding up the parietes of the uterus, squeezed out the injection from its sinuses, the apertures upon the interior surface of the uterus offering no resistance; whilst the same injection, compressed to an equal degree in the interior of the placenta, was still detained, notwithstanding the incision which had been carried quite through the organ which contained it, and into which it

has been alleged to have been merely extravasated. The difference forces conviction upon my mind, that, in the latter case, a cellular apparatus entangled the injection. The small masses or nodules which I have described were also seen and distinctly recognized by Messrs. Beevor, Corfe, and Elwyn, who were present at this examination, and the illustration used by all to convey an idea of what we saw, proved that the appearance which presented itself to each of us was similar, or identical. So one described it as like the corpora cavernosa penis, without being aware that this was the illustration repeatedly used by the Hunters in explanation of the mode of circulation; another considered it to resemble the minutest cavities in the cellular tissue of the lungs, injected with red injection; whilst to myself, the textures in the human body which it instantly suggested were the hyaloid tunic in the eye, and the peculiar membranes which entangle fat and marrow in their interstices. All, therefore, in their illustrations and expressions, avowed their impression of the existence of a cellular tissue, and consequently agreed in the belief that the red injection was therein deposited, and that this tissue, formed of a most delicate pellucid membrane, must have so entangled the injection as to prevent its escape upon the application of pressure. All, too, saw circulating upon and amongst these granules the minute ramifications of those blood-vessels which had been filled with the yellow injection. I have since repeatedly, and often in the presence of others, examined, through a microscope of considerable power, different portions of this placenta; and each succeeding examination tends but to corroborate the accuracy of my first observations. The minute subdivisions of the red injection into granules, or nodules, is most conspicuous, and they are evidently entangled in and about a membranous substance, which strong spirit has, with the decidua upon the surfaces, rendered less transparent and of a pearly lustre, whilst close to, and often upon, these minute masses, may be equally distinctly traced the slender lines of yellow injection contained in the ultimate ramifications of the vessels of the cord.

The examination of recent placenta, immediately after their expulsion from the uterus, affords also very strong cor-

* Observations on certain Parts of the Animal Economy, p. 135.

roborative evidence of the existence of this cellular tissue. For this purpose it is requisite to select a placenta which has been subject to very little pressure in its expulsion and extraction. The vagina, then, must have been capacious and relaxed; a single and slight uterine effort must have sufficed for its expulsion from the cavity of the uterus, and only the smallest assistance by traction of the navel-string have been required to invert the placenta, and thus preserve its internal surface from violence in its course. Without attention to these points, the placenta will be nearly drained, and its internal texture appear to be made up almost entirely of white strings (the blood-vessels). It will contain very little blood, the greater part having been squeezed out by the reiterated contractions of the uterus, the pressure of the vagina, or the rough handling of the practitioner. Not so, however, under the more favourable circumstances I have enumerated: such a placenta, washed by the most gentle shaking in tepid water, into which it should be at once put, without even allowing it to rest upon any solid body, and before the blood has time to coagulate, will present upon its surface a dark purplish colour, and if gently torn by bending the fetal surface back upon itself, avoiding all pressure upon the part which gives way, the lacerated surfaces look like a torn mass of currant jelly, confined in some texture which allows but little to escape, and that little drop by drop, like the vitreous humour from its hyaloid membrane, or the transparent gelatinous fluid from a similar membrane in a large navel-string; or, if further illustration be required, like lymph from a vaccine pustule. The vessels are not immediately visible; but if, with a little water dropped gently from the hand upon the rent, the blood be then washed, the whitish vessels stretching across the rent, most of them being entire, come into view, and resemble exactly those which are at once visible upon tearing in a similar way a placenta which has been the subject of more compression. This experiment I have again and again repeated, and always with the same result. In both placentae, however, (as well that which is drained of its blood as that which is still full), the circumstances connected with the vascular part were similar;

the vessels of the navel-string had been tied upon the birth of the child in both. In one, however, blood remained entangled in some texture so as to hide the vessels; in the other the blood-vessels came immediately into view. In the former the placenta had sustained little or no pressure—in the latter the compression was considerable; in the former the blood remained—in the latter it was gone. No one can well doubt that the pressure had caused the blood to escape in the latter case. But it may be asked, whence did the blood escape? Not from the vessels, because these were tied, and they do not penetrate the deciduous membrane so as to allow the escape in that direction. It must, then, have been from the interstitial texture exterior to the coats of the vessels which the experiments and observations of the Hunters prove to have a direct communication with the maternal, but not with the fetal vessels, and which, there cannot be a shadow of doubt, also held the red injection in the placenta which I have described. To me, too, it appears almost equally manifest that this peculiar substance has more or less of a cellular character, and that the blood which, in the recent placenta, it was seen to contain, inasmuch as that blood was exterior to the coats of the vessels, and not within these canals, must of necessity have come from the mother.

I am well aware—for it were folly to affect ignorance upon such a subject—that this view of the structure of the placenta has been of late much controverted. It has been said, upon authority for which I entertain, and would wish therefore to shew, respect, that “the placenta consists SOLELY of a congeries of the umbilical vessels covered on the fetal surface by the chorion and amnion, and on the uterine surface by the deciduous membrane*.” But this description is incomplete and inaccurate; it omits altogether that layer of decidua which I have shewn, upon the authority of others, as well as by my own observation, to exist between the chorion and the fetal surface of the placenta, and excludes even those white filaments which run in various directions and connect together the ramifications of the umbilical arteries subdivided to an al-

* Dr. R. Lee, in *Philosophical Transactions*, 1832, p. 60.

most indefinite extent; the existence of which is admitted in the same paper *. These, indeed, appear to me virtually to concede the existence of an interstitial substance of a cellular tissue; for if "the ramifications of the umbilical arteries," (*and veins?*) subdivided to an almost indefinite extent, "are connected together by white slender filaments, running in various directions," it is clear that these filaments must be at the least as numerous as the vessels which they connect—that they must interlace each other in every conceivable direction, and must have spaces between them; which spaces are neither more nor less than the cells of the Hunters, or "the cellular texture" seen by Dr. Nimmo, in the Glasgow preparations, full of injection; which, however, he believes to have entered at some weak point of the second layer of decidua upon the placenta, by a laceration which, however, he seems to have been unable to detect. Nor is this interstitial substance very differently described by William Hunter, who represents it as consisting of "a thousand irregular processes, which pervade the substance of the placenta, as deep as the chorion or inner surface, and are every where so blended and entangled with the ramifications of the umbilical system that no anatomist will, perhaps, be able to discover the nature of their union †." Indeed the only distinction in the description of each is, that Dr. R. Lee represents them merely as *connecting filaments*, without tracing them to their source, or hinting at their distribution and its consequences, whilst Dr. Wm. Hunter, with that minuteness which characterizes him, declares them to be productions of the decidua, "shooting out into innumerable floating processes and rugæ, with the most *irregular* and most minutely subdivided cavities between them that can be conceived." Dr. R. Lee, then, errs only by omission, but, as far as he goes, rather corroborates than controverts the accuracy of Dr. Wm. Hunter; which appears, moreover, to be further established, if that were requisite, by the experiments which I have had frequent opportunities of making upon the recent, and also by repeated microscopic observations

upon the injected, placenta. In the smallest fragment even of the latter, these processes, constituting no small portion of the mass examined, were still detected. Whether the incision was carried vertically, horizontally, or obliquely, in the direction of or across the vessels, the membrane, semitransparent and pearly, from the spirit, was still abundantly conspicuous, and probably identical with the white filaments admitted by Dr. R. Lee; with "the thousand irregular processes," and "the innumerable processes and rugæ, with the most irregular and most minutely subdivided cavities between them," of Dr. Wm. Hunter. These processes, however, though distinct in every part, were even more obvious, because greater and more numerous, in the direction of the edges and of the sulci; which latter may be justly considered as the edges of so many "placentulae," and have always a very oblique direction, much corresponding with those portions of decidua which are still attached to the uterus, which present a lamellated appearance, and which lead towards those openings of the uterus which enter also obliquely into the veins or sinuses.

It thus appears that the placenta is made up, not only of the ramifications of the vessels which proceed from the umbilical cord into its substance, but of two layers also of deciduous membrane—the one upon the uterine, the other upon the fetal surface; that, connected with these layers, and proceeding from them, minute processes are continued through every part of its substance; that these processes, shooting in every direction, and therefore decussating each other, must of necessity leave cavities or spaces between them; that these spaces may be filled by injection thrown into the spermatie arteries of the mother, without the slightest evidence of laceration or extravasation; and that, in the recent placenta, these spaces are full of fluid blood, which is exterior to the coats of the vessels, and therefore must come from the mother.

These are facts within my own knowledge, because established by my own personal experiments and observations; and they seem not unimportant as contributing to the settlement of a question which has been recently agitated with all the keenness and acrimony of personal controversy.

† Wm. Hunter on the Gravid Uterus.

I may not, perhaps, have added largely, if at all, to our previous stock of knowledge upon these subjects: the facts which I have recorded have at least, a claim to authenticity. In some points they differ slightly from the descriptions of the Hunters; but even these differences tend rather to supply omissions than to correct inaccuracies. In the main points they afford very unequivocal evidence of the anxiety of those great physiologists, whose character has become a species of public property, to be minute in their researches, and accurate in their statements and conclusions; and although they must be acknowledged to be somewhat at variance with the opinions of some of my cotemporaries, I am fain to acknowledge that hitherto I have seen and heard nothing which is calculated to convict those great luminaries in physiology, of error, or misconception, in the doctrines which they have advanced, upon the intricate subject of the structure and office of the placenta.

FELINE MONSTROSITY.

To the Editor of the Medical Gazette.

SIR,

IF you consider the subjoined extraordinary case of *lusus nature* worth recording, you are at liberty to insert it in your journal; and should any sceptical person make application at your office, desiring to be further acquainted with the facts, you have simply to refer him to me, and he shall have ocular proof of the truth of my statement.

On the 13th instant, a plumber's cat, in Horseferry Road, Westminster, at her *accouchement* brought forth three kittens, all exhibiting strong characteristics of the monkey tribe, as evinced by the general conformation of the head, the peculiarity of the hands or paws, the position and shape of the ears, the structure of the pelvis, and the facial angle. It would seem that either copulation had taken place between a monkey and cat, which may be conceived to be improbable, considering the specific organization of the parts; or, more probably, that a fright, in the early period of conception, had produced this most singular effect.

Formerly it was a generally received opinion, that oddities of the above na-

ture were not primordial or aboriginal, but that they were caused subsequently by the power of the imagination transferring the imperfections or hideous character of some external object to the offspring in the womb. Will not the present case go a little way to prove a most abstruse physiological point—whether in the human species, as in the brute creation, sudden fright, or sight of something detestable, may not induce some derangement in the principle of growth? This opinion, it is true, though sedulously maintained by many physicians of eminence, has been partly disproved by common observation as well as by philosophy. There are no positive proofs to support it, but there are many strong negative facts.

There is at present in the museum of the London University a preparation of a human fetus, with a face the perfect resemblance of a pig. Here I conceive the imagination must have had some influence in conveying the impression to the child. I leave this, however, for physiologists to determine.

From this digression I shall come more immediately to the notice of the accompanying sketches, which are given with great fidelity; the one exhibiting a side view, the other a front view. Two of these kittens were furnished with no other eccentricities than what have been mentioned; but the third, a species of monocus, forcibly brought to my recollection the mythological idea of the Cyclops: the single eye in this instance was placed in the middle of the forehead, as seen in fig. 1, *a*, with total obliteration of the nose, as referred to—*a*, *b*.

When we consider the caprices and anomalies sometimes displayed by nature in the formation of animals, and the effects which these must have been calculated to produce in times when science was less advanced than it now is, we may probably see in them sufficient to account for the exaggerated descriptions given by writers whose general fidelity is nevertheless acknowledged. Thus Pliny observes, when he treats of *Æthiopia**, that the Blemmyes have no heads; that their eyes and mouths are placed upon their breasts; and that some who are destitute of heads have their eyes placed upon their shoulders. He also advances†, upon the authority

* Lib. v. chap. viii.

† Lib. vii. chap. ii.

of Eudoxus, that in some parts of India the men have their feet an ell long, while those of the women are so small, that they have the name of struthopedes, sparrow feet; and also, that the ears of

some are so long and broad, that they can hide themselves behind them.

Your obedient servant,

J. C. ATKINSON.

c, The ear, turning back, as in the monkey.

FIG. 2.

SUGGESTED IMPROVEMENTS IN THE APOTHECARIES' ACT.

To the Editor of the Medical Gazette.

SIR,

THE Apothecaries' Company, in their late memorial to Lord Melbourne, have not been slow to sound their own praises. They begin by informing his Lordship, that "their regulations have most essentially improved the schools of medicine in England, *as well as the state of medical science in general*;" and they farther assure him, "that they have administered the Act of 1815 *impartially, honestly, properly, and efficiently*, as they are prepared to shew, should an opportunity be afforded them, which they trust it will." Most sincerely do I join in the hope that Government will give them such an opportunity, for nothing short of that will, in my view of the matter, effectually quiet the agitation into which the minds of the profession in the three kingdoms

have been thrown by the contemplated changes in the Apothecaries' Act. A select committee of either the Lords or Commons, empowered to inquire into the provisions of the Act of 1815, and to report, if any, and what amendments in it are expedient, would, I am persuaded, be a most useful measure; indeed, I do not see how the Government can well do without some such preliminary inquiry. We should then know how far we can place reliance on the answer which the Scotch Colleges are prepared to give to the memorial of the Apothecaries' Company, and which, as far as I can learn, is to the following effect:—

1. The Colleges of Physicians and Surgeons of Edinburgh do *not* interfere with the graduates or licentiates of any other British College, who, in so far as they are concerned, are permitted to practise and dispense medicines to their patients in all parts of Scotland. It is true, there are some old laws giving them the power of summons and examination; but these laws are obsolete, and neither are acted upon, nor have been so, within the memory of man.

2. The Faculty of Physicians and Surgeons of Glasgow obtained some time ago, from Government, a power to examine the graduates and licentiates of other Colleges proposing to settle and

practise in four of the western counties of Scotland; but they do not require that such gentlemen should previously have served a five years' apprenticeship to *one of their own body* (as the Apothecaries' Company interpret one of the clauses of the Act of 1815); and besides, they have intimated their willingness to relinquish this obnoxious privilege, if their graduates are exempted from the operation of the Apothecaries' Act in England.

3. The Scotch Colleges deny that any complaint was ever made of injury to the public, from their licentiates practising undisturbed in England prior to 1815. The Apothecaries' Act was not passed, say they, with any reference to the Scotch practitioners, but to guard the English public against the defective education of the London schools, and persons practising without any license whatever.

4. They maintain that the Scotch system of education is more extensive, and their examinations more searching, than those of the Apothecaries' Company; and that if men, bred in the Scotch schools, are willing to undertake general practice, and to come into competition with the Apothecaries' licentiates, it is for the interest of the public that they should be allowed to do so.

5. With regard to the injury which the Apothecaries' memorial states will be done to the numerous schools of medicine recently established in the provincial towns of England, by the projected changes in the Act of 1815, they reply:—Either this provincial education is better than the Scotch, or it is not. If it is better, the Scotch licentiates will not succeed in competition with their English rivals. If it be not better, it must be worse, and ought not to be supported by law, to the obvious detriment of the public.

These, sir, I understand to be the chief grounds on which the Scotch Colleges claim the interference of the legislature, in opposition to the Apothecaries' Company, according to whom every thing connected with medical education in England is perfect. That the Apothecaries' Company have meant well, and that they have acted throughout most impartially, must be at once and most freely conceded: but some of their measures, especially some of their *recent* measures, are far from meriting such unmixed praise.

The Act of 1815 prescribes four things as necessary prior to the student's coming before the Court for examination:—1st, That he be of the age of twenty-one years. 2d, That he produce testimonials of good moral conduct. 3d, That he shall have served an apprenticeship of not less than five years, to an apothecary. And 4thly, That he shall produce testimonials, to the satisfaction of the Court of Examiners, of a *sufficient medical education*.

The two first of these qualifications admit of no argument or dispute; the third has been discussed in a former letter. Let me now, then, offer a few reflections on the fourth and last of these requisites.

When your readers call to mind the almost interminable series of rules and regulations for the guidance of the English student's education, which during the last twelve years have issued from Apothecaries' Hall—when they reflect that all the provincial schools throughout England have been framed to meet those regulations, and that, in point of fact, the Apothecaries' Company have the complete control over them—it will scarcely be credited that this immense mass of power and influence is founded on that single word of the Act of Parliament—*sufficient*. Yet there is no other clause in the Act bearing upon this point, or giving them in any more specific terms the power of regulating the education of their licentiates; all is summed up in the single but expressive word, *sufficient*. The Apothecaries' Company are constituted, by the Act, judges of what is a *sufficient* medical education, and they have certainly taken a most comprehensive view of the meaning of that word. I can perfectly understand, that Parliament intended them to define what was the *kind*, and what the *extent*, of study necessary to be undergone by each student prior to examination; but I confess I am unable to trace in this word any adequate authority for that system of interference with the minute *details* of medical education which the Court of Examiners have adopted of late years. Of this kind are the regulations touching the order of succession in which the several lecturers are to be attended, and those which refer to the mode of signing the certificates. If this system of petty interference is to be continued, the Court of Examiners will probably next issue an

edict, regulating the order in which the teachers of medicine shall take up their respective subjects, and the number of lectures to be appropriated to each.

It was the proceeding of the Apothecaries' Society to which you doubtless alluded in a former No., when you stated them to be "occasionally somewhat too busy and pragmatist." Every one will be ready to acknowledge the good they have done; but, judging from some recent occurrences, they would seem to be deeply tinctured with the prevailing mania for ultra legislation. A young man who has been an apprentice five years, might surely be permitted, without incurring a penalty, to attend the practice of physic before *matéria medica*, if it happened to suit his convenience: and with respect to the new mode of signing the certificates, it serves no other purpose, that I know of, than that of distracting the minds of pupils, and keeping their attention more alive to the *forms* of education than to its substance.

Several regulations of the Court of Examiners, which are free from the sin of being frivolous and vexatious, are yet, on other and not less substantial grounds, open to serious objection. I would more especially advert to the great and undue importance attached by the Court to the study of medical and general botany. Its application to medicine is hardly superior to that of mineralogy or meteorology: it is more the study of names than of things, and occupies time that would better be devoted to matters more immediately subservient to practice. I object also to the newly-introduced class of medical jurisprudence. It increases the expense of medical education, without any corresponding benefit to the public. Nine out of ten of those who lecture on the subject, are compelled to have recourse to books for all their facts and all their reasonings. They have no means of adding, from personal experience, to the information thus obtained. Not one of them, perhaps, was ever in a court of justice in his life. The science consists altogether of dry details, which the student forgets the moment the lecture is over, and which he may practise fifty years without ever having occasion to require. The question is, not whether such a branch of study may usefully be prosecuted at a University, where the period of education is extended to four years, and

where one man may be found to devote himself almost exclusively to it (as Dr. Christison did in Edinburgh), but whether it is adapted for the education of general practitioners at fifty different schools, where the period of study extends only to two years, and where, with a large proportion of the pupils, all possible economy of purse, as well as of time, is desirable.

I attribute much of all this superabundant interference in medical education, on the part of the Court of Examiners, to there being no *Cour d'Appel* prescribed in the Apothecaries' Act. Whatever the Court of Examiners lay down, is *law* without appeal. Surely, in any revision of the Apothecaries' Act which the legislature may undertake, it would be desirable that the Colleges of Physicians and Surgeons should co-operate in any regulations which it may be thought desirable to adopt, with reference to the management of medical schools throughout England. This might be effected in two ways: 1st, by making the sanction of those Colleges necessary for legalizing any regulations which the Apothecaries' Company may suggest; or, 2dly, by altering the composition of the Board of Examiners, and making it consist, not (as at present) of twelve apothecaries, but of four physicians, four surgeons, and four apothecaries; to be nominated by the Secretary of State.

I am, sir,

Your very obedient servant,

MAXILLA INFERIOR.

London, May 25, 1833.

MEDICAL GAZETTE.

Saturday, June 1, 1833.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THINGS AS THEY WERE BEFORE 1815.

HOWEVER imperfect or defective the Apothecaries' Act may be, there are few, we believe, in the medical community, who would not deplore a recurrence of the circumstances which created a ne-

cessity for that Act, and led to its adoption. Little more than twenty years have gone by since those circumstances were at their height; yet twenty years, for the public at large, as well as for no small portion of the rising generation of practitioners, would seem to be as productive of oblivion as if they had been two hundred.

One certain consequence of making those sweeping alterations in the Act which the Scotch Colleges contemplate, would obviously be to bring back that state of things which is now so ill remembered, and to render the condition of the large and respectable class of well-educated practitioners throughout the kingdom, even much more intolerable than their predecessors found it; and *they* had to stir heaven and earth before they were able to rid themselves of their burdens. Not that the said predecessors were a whit more energetic in the commencement of the struggle than are the present race: overrun as the country was by hordes of unqualified pretenders, who disputed, we may say, every inch of ground with the more honest practitioner, the contest maintained by the latter, however successful in the end, was miserably defective of energy in its rise; and the feeling of apathy with which grievances were endured, can perhaps only find its parallel in the indifference which at present seems to prevail among the regular practitioners of England and Wales, regarding the state of insecurity and primitive barbarism with which they are threatened.

In order to jog the memory of this indifferent and apathetic class, so oblivious of the transactions of twenty years ago, we will take leave to mention a few facts connected with the history of the Act of 1815. The operation, indeed, of that legislative measure has been so effectual in removing every thing like the old grievances to which

we refer, that every recent allusion to them has somewhat of an historical air about it, as if it were a tale of the times of old. Some, no doubt, will tell us that we overrate the matter, and that occurrences of a similar nature have by no means been unfrequent in various parts of the kingdom since the passing of the Act; but this we take to be a mistake. Any resemblance fancied between the latter state of things and the former can amount to little more than that of the shadow to the substance, or of the echo to the primitive sound. Any thing like a *grievance* in the state of the profession, arising out of the Act of 1815, or affecting more particularly the state of the general practitioner, can, we imagine, be with difficulty substantiated. Quacks, it is true, and great quacks, have contrived to evade the law even under the very eye of the Society of Apothecaries; but before this be imputed as a serious charge to the guardian body, it ought first to be shewn, that the powers bestowed upon them could be brought to effect the suppression of crafty offenders like those alluded to. In ordinary cases, and those very numerous too, ample protection has been afforded the public; and it may be a question, whether the fact of the escape of a few delinquents, endowed with superior cunning, may not have the same relative weight as a little knot of exceptions has to a general rule. There has, in short, been of late years, on the whole, a period of great comparative, if not positive, tranquillity,—of comfort with respectability, enjoyed by the regular practitioner. The public, too, has had little to complain of; and if perfect protection has not been afforded, time at least, and the gradual ameliorations arising from a riper experience, have been manifestly effecting that desirable consummation. But to revert to our purpose:

Without going farther back than the first ten years of the present century, we

may briefly state what opportunities at that time existed with regard to medical education, and whence the public derived their principal supply of hands to minister to them in sickness and bodily suffering. Even at that period there was in London a small, but what might be considered a competent, school of medical knowledge; and a number of young men were sent to the metropolis annually, from various parts of England and Wales, to go through a respectable course of study, and to furnish themselves with the certificates of well-known lecturers, and celebrated hospital surgeons. The generality of these students usually returned to their native quarters, as well qualified to enter on practice as their age and opportunities permitted; and having imbibed at least a certain quantity of sound principles, they could profit by their subsequent daily experience; and by attentive observation of their professional opportunities, many of them became able practitioners, and some attained no inconsiderable degree of reputation.

But this was, as might be presumed, a small and select portion of the numbers who were required for country practice, or even of the number who professed to avail themselves of the source of qualification just mentioned. Many young men came to London, merely to secure a title for having done so, while others remained for so brief a space as to be unable to derive any advantage from their journey; and perhaps, in addition to this, having been ill prepared by preliminary exercises for improving themselves abroad, they returned home to practise nearly as wise as when they set out. All this time, be it observed, that, for those who were to practise the medical art on the king's lieges in distant parts of the country, and among the lower and middling classes in all parts, there was no tribunal by which their sufficiency in the prae-

tice of medicine and midwifery was to be ascertained. Both the diligent and the indolent, the competent and incompetent, who but complied with certain formalities like those just described, were all deemed equally qualified in a legal sense—that is, wherever a legal power, in the shape of a little brief authority, took cognizance of such persons practising physic in the community. Where it was obliged to take cognizance of such persons, and ought to give a preference to the better qualified, it is mortifying to state, that sometimes both classes were overlooked, and dealings were entered into with impudent impostors. In the business, for example, of providing for medical attendance on the parochial poor, it was the custom of the overseers of that day (and we fear the same system is but too frequently acted upon still), to receive tenders every Easter for taking care of the sick poor of their district; and on those occasions, regardless of all comparative merit, the lowest bidder, no matter who, was the successful candidate; and thus the parish doctor—it signified not whether his practice previously was confined to the brute or the human part of the creation—became a legitimate practitioner, by virtue of the humility of his claims to remuneration.

There was, perhaps, a necessity for such appointments in some parts of the country; for any thing like a supply of regular practitioners was not every where to be found. We have before us a curious statement relative to the numbers of educated and uneducated persons who were practising in a populous part of Lincolnshire in the year 1804. It appears that in a district, including the market-towns of Horncastle, Spilsby, Alford, and Tattershall, there were five physicians (graduates of Scotland), eleven surgeon-apothecaries, twenty-five druggists, forty irregulars of both sexes, over and above the druggists, and

sixty-three midwives, not one of whom had received any instructions; making an aggregate of 144 persons exercising medicine for gain in that district, of whom only *one in nine* had been previously educated for the profession. In the Market-Razon district, comprehending the market-towns of Wragby, Razon, and Castor, there was no resident physician: there were seven regular practitioners (surgeon-apothecaries), nine druggists (*one* of whom had served an apprenticeship), seventeen irregulars of both sexes over and above the druggists—one of the men followed midwifery; there were thirty-two midwives, not one of whom had received any instructions: in all, sixty-five persons exercising medicine for gain, of whom *not one in nine* had been previously educated for the profession. And the example of Lincolnshire may serve for that of other counties*.

The reflection on these facts, made by the writer from whom they are borrowed, is just. "When it is considered," he says, "that each (uneducated) individual, through ignorance of proper means, or the misapplication of active remedies, may destroy at least one person annually, and ruin the health of many more, what a frightful calculation of human affliction forces itself upon our notice!"

Now will any one venture to say that the country was not in want of a protective measure, such as the Act of 1815, when nearly nine-tenths (as we have seen) of the persons who undertook to minister to the bodily ills of the people were uneducated pretenders? So habituated, however, were the better order of practitioners to the state of things in which they found themselves, that, though there were grumbings from time to time on minor points and matters of

petty policy, no step was taken, nor even contemplated, until an affair of pecuniary, and now almost of ludicrous, interest, roused up the latent energies of that part of the profession which was immediately affected—the surgeon-apothecaries.

It so happened, in the year 1812, that the Minister was obliged to lay a heavy additional duty on glass; and the consequence of this was immediately anticipated, by the apothecaries of the metropolis, as threatening a material diminution of their profits. They were stirred up: a public meeting was called; Mr. (now Dr.) Man Burrows took the chair; a string of resolutions passed unanimously, which strongly deprecated the injury about to be inflicted on them by the impost in question. A committee of the leading men was appointed, and the important business assigned to them to consider was, what might be the best means of obviating the calamitous rise in the tax on phials.

Though this influential body was, we believe, not successful in warding off the dreaded impost, it did not break up without effecting an object which will be memorable in the history of the profession in England. The glass-bottle committee was the very body which had the state of the profession brought before parliament, and which did not close its labours until the Bill of 1815 was past. Who (when he thinks of a tax on phials leading to the Apothecaries' Act) will not be reminded of the circumstances connected with a certain other act of settlement and independence, growing out of an impost on tea?—But once more let it be clearly understood, that we speak of this protective and regulatory measure, not as one free from imperfections, but simply as a measure which has done the state good service, in limiting the encroachments of unqualified pretenders—in securing a succession of well-educated

* From an able Tract, entitled, "An Inquiry into the present State of the Medical Profession in England, &c." 1814, by Mr. (now Dr.) Kerrison.

practitioners — and in advancing the standard of education.

And this is the measure which, without an attempt to apply to it the obvious reforms of which it is susceptible, is to be virtually abolished;—this is the Act which, after having protected the public for so many years, is now to be virtually discarded;—this is the Act, on the faith of the stability of which a large number of practitioners, having entered into the profession with considerable expense and more than ordinary labour, in complying with the requisite forms, is to be virtually repealed,—and they, the said practitioners, left unprotected, to contend for their bread with whatsoever intruders may set themselves up against them!

One would think that good reason ought to be shewn for meddling with an enactment which is of so much consequence to the public, and which so vitally affects the welfare of above 10,000 medical practitioners settled throughout England and Wales. The public, however, would seem to care little how “the doctors” settle matters among themselves; their attention is absorbed with other objects, and perhaps they are but ill qualified to give an opinion on the subject. The government, probably, will give the matter due attention, and remedy defects and settle the claims of parties, as may be most expedient for the public good. But what can be the result of any complaint about injury, or threatened wrong, when the person alleged to suffer not only does not come forward and shew that he feels, but when no direct murmur is heard to escape his lips? This apathy is surprising. Is another tax upon glass, or a glass-bottle committee, required, to point the way, not to rights to be acquired, but to the common protection and security?

We are glad to perceive, however, that though the parties whose privileges

are directly aimed at are indifferent and silent, their security is not unheeded by the body which conferred those privileges. An official reply to the Statement of the Edinburgh College of Surgeons has appeared. It is a document much better calculated to vindicate the working of the Act than the memorial was, which we published about a fortnight ago in this journal, along with the Edinburgh Statement. In another number we propose to give the subject further consideration, and to notice this and other documents which have recently been published.

COLLEGE OF PHYSICIANS.

May 27, 1833.

THIS was one of the most brilliant and crowded meetings which has taken place this season—being honoured by the presence of his Royal Highness the Duke of Sussex, several distinguished noblemen, his Grace the Primate of Ireland, some of the English bishops, Lord Chief Baron Lyndhurst, most of the judges, and numerous eminent members of the church, the law, and the medical profession.

A paper, which excited general interest, was read with great animation by the learned President: it was entitled,

On the Deaths of some Illustrious Persons of Antiquity. By SIR HENRY HALFORD.

Sir Henry began by observing, that when our feelings have been captivated by the history of the transactions of an illustrious life, the mind is unsatisfied while any thing yet remains to be told of the person who has engaged it. But, in addition to the sources of interest presented to others, the physician may find, in the subject of the present paper, many facts connected with the operation of medicines, known in former times, and be enabled to correct some misapprehensions regarding the true nature of the diseases of which some of the illustrious ancients died.

Sylla, the dictator, died of an internal abscess, which burst during a fit of passion. He had set his heart on the re-

storation of the Capitol and its dedication on a particular day; but a messenger having brought him intelligence that his expected resources had failed, he gave way to a paroxysm of rage, was seized with a vomiting of blood, passed the night in great suffering, and died next day;—an awful example, observed the learned author, to those who take no pains to control their passions, and especially impressive on those who, with violence of temper, combine any thing weak in their structure.

Crassus, the lawyer, and friend of Cicero, died of pleurisy. He was speaking in the senate when he was seized with pain in the side. On going home, he had a shivering fit, followed by fever: he died on the seventh day. It is not mentioned what means were had recourse to with a view of preserving his life; but as Celsus, who lived a few years afterwards, recommends bleeding, cupping, and blistering, in inflammation of the chest, it is probable that these were adopted.

Of Pomponius Atticus, beloved by Cicero, and esteemed by all parties even in the most distracted condition of the state, we are told that his mortal disease was a fistula in the loins; probably, observed Sir Henry, a dysentery, ending, as it sometimes does, in ulceration of the lower bowel, for he is described as having had tormina and tenesmus. Finding his disease increase, notwithstanding the use of the remedies prescribed for him, he called his friends together, and informed them that he had made up his mind to take nothing more, whether food or physic; and rigidly adhering to his resolve, he died on the seventh day, at the age of 77. This resource of starvation under incurable disease, seems to have been frequently adopted by the Romans; and Pliny mentions an afflicting case in which he was sent for by the wife of one of his friends, to dissuade her husband from his purpose; but he arrived too late. The death of Socrates is familiarly known to have been effected by a narcotic poison; but the precise nature of the substance used is matter of conjecture. The Greeks, we know, were acquainted with the aconite, the black poppy, the hyoscyamus, and hemlock. The henbane is used at Constantinople, and, Sir Henry believes, also throughout the Morea, under the name of Nchensch; which sounds so much like *νηπενθη* as

to recal it irresistibly to our minds, and to lead to the suspicion that hyoscyamus had been used as a narcotic from very early times. But with regard to Socrates, it is probable that the same poison was employed in the cases of other persons condemned to death—viz. *κωτειον*, *cicuta*. Dion, the father of Dionysius, and Phocion, were both poisoned with hemlock, and it is mentioned by Theophrastus that the whole plant was pounded together; but the Chians peeled off the rind, as apt to occasion pain, and then made an infusion of the other parts. The poison, at all events, was weak, and slow in its operation; for the executioner told Socrates that it would prevent its effect if he entered into earnest discussion, and that it was occasionally necessary to repeat the dose three or four times. The death of Hannibal next occupied the attention of the learned author of the paper. The poison, we are told, was contained in a ring, and what it was we shall probably never know with certainty,—though modern chemistry might furnish many which would not exceed the prescribed bulk—as prussic acid. Probably, however, in this instance it was some of the products of *Lybia*—*Lybia ferox venenorum*—which supplied the illustrious Carthaginian with the means of death. But as to the mode in which Britannicus was destroyed by Nero, Sir Henry Hallford is of opinion that we may rationally conjecture the poison to have been laurel water. Locusta, a female poisoner, kept for state purposes, was employed to prepare a dose which should prove instantly fatal; and after having been tried on a hog, which was in a moment killed, it was administered to the unfortunate victim at a banquet. He was seized with an epileptic fit, and expired. This account was then compared with that of the death of Sir Theodosius Boughton—a detail into which we regret that our very confined space prevents us from entering farther than stating that an extraordinary blackness was observed over the face of Britannicus, and that the learned President remembered having seen Sir Theodosius Boughton after the body had been disinterred for examination, and that the face was, in colour, like a pickled walnut.

In the case of Alexander the Great, there was a story of his having been poisoned, and that the poison had been sent to him by Antipater, in the hoof of

a mule; but if conveyed at all, it was in an onyx—such as was used to hold precious ointments—for *ovvξ* signifies, not only the precious stone of that name, but also *unguis*, the first sense of which is the human nail, and the second the hoof of a horse or mule; which meaning had been given to the word in reference to the alleged conveying of the poison, instead of the stone in which ointments were kept. Alexander, however, in fact, died of a remittent fever, of the progress of which daily statements were made—constituting the first example which we find of recorded bulletins. He died on the eleventh day.

Sir Henry Halford proceeded to pass an encomium on the genius of this extraordinary man, and upon the sagacity of the policy by which he retained the dominions he had acquired; this he compared, especially in regard to the plan of appointing Macedonian officers to command the native troops, to the system at this day adopted in India. The field thus opened was wide and inviting; but, said the learned author, in conclusion, “I must not forget that my theme was not *the lives*, but *the deaths*, of some illustrious persons of antiquity.”

RECLAMATION REGARDING THE VALETUDINARIUM.

To the Editor of the Medical Gazette.

SIR,

In your observations on the letter of the correspondent who has called your attention to “a series of laudatory articles on the Gower-street School, which have appeared in the *Times* during the last month,” you stated, “that one individual who has lately taken up the cause is a friend of the Editor, and a frequent contributor to the paper;” and you were pleased to add, “that the thing has been too much overdone, not to be attributed to private influence, even if the gentleman alluded to had been less communicative regarding his influence with —, the *Redacteur en chef*.”

That I have the happiness to number

the Editor among my private friends, I readily acknowledge; and I trust that I shall always retain his friendship and esteem. That I am a frequent contributor to his paper, is also equally true; but it is always in the character of a correspondent, writing on subjects in which the public are interested. On this account only have my communications *not* been disregarded. I must, however, beg to deny, and in the most unqualified terms, that I have, either in public or private, stated that I have any influence, directly or indirectly, with the gentleman whom you are pleased to term the “*Redacteur en chef*,” or any other person connected with the *Times* paper, in obtaining admission for any articles or paragraphs for the support “of any private speculation;” and I beg to add, that I am *not* the author of any “laudatory articles on the Gower-street School.”

Connected for sixteen years, as a clergyman, with the metropolis and its neighbourhood, and believing that in lending my feeble assistance to the institution in progress I was aiding in giving relief to the wants of a numerous population insufficiently supplied with such an asylum, I readily consented to advocate its cause at Christ Church, and subsequently to prepare and offer up a prayer on laying the foundation stone; and I trust, in so doing, I have [not] stated or written any thing unworthy the station I am placed in as a christian minister.

Yours obediently,

C. WODSWORTH.

May 30, 1833.

[We, of course, give immediate insertion to the preceding letter, though, from the very late period at which it was received, it has cost us some trouble to do so in the present number. The statement of Mr. Wodsworth appears to us to be so very evasive as to leave the matter precisely where it was before, with the exception of those parts of our observations which it tends to confirm. We did not assert that Mr. W. was actually the “author” of the laudatory paragraphs alluded to, but only that they were the result of private influence, and knowing his connexion with the paper, and his activity about the hospital, we expressed our belief that

his representation in its favour had been the immediate cause of their appearance. Again, it is nothing to say that he never "stated" that he had any influence with the Editor, for it is easy to communicate to others a knowledge of such fact without making a *statement* to that effect *totidem verbis*. Suppose, for example, any one were to mention that he had spoken to his friend, Mr. —, about appropriating the money collected for the late Queen Caroline to the use of the University hospital, would not the fair inference be, both that he did possess influence with the person alluded to, and that he had made use of it? We never said, nor implied, that either Mr. Wodsworth, or the Editor in question, had any thing to do with the Valetudinarian, as a "private speculation;" but we asserted, and we repeat the assertion, that it *is* such, having been actually set forth by the Council as one of the plans by which the finances of the University might possibly be bettered. Neither did we find fault with Mr. W. for "aiding in giving relief to the wants of a numerous population insufficiently supplied with such an asylum:" our criticism was directed against advocating, as a charity, the cause of a joint-stock company; and holding up, as meritorious, on the part of the medical men, an act which was indirectly, though most palpably, intended to put money in their pockets. Again, we deny that the intended hospital can afford any such "asylum," or, if designed for purely benevolent objects, would ever have been placed in its present situation—would ever have been planned on its present scale—or would ever have been commenced with its present means. In conclusion, we did not allude to Mr. Wodsworth's being an acquaintance and friend of the Editor, as any taunt, which he would seem to imply, but as affording a rational explanation of a line of conduct at variance with that usually adopted by the *Times*, and in contradiction of its previously declared intentions on this particular subject; and we must take leave to add, that nothing in Mr. Wodsworth's letter is calculated to remove this impression, however his modesty may lead him to disclaim his possessing influence in the quarter alluded to.—*Ed. Gaz.*

WEEKLY JOURNAL

OF
Medicine and the Collateral Sciences.

SATURDAY, JUNE 8, 1833.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

DISEASES OF THE CHEST.

PNEUMATO-THORAX.

Impropriety of the term employed by Laennec.—The pleura is sometimes distended by another fluid—air. This disease is called by Laennec *pneumo-thorax*, but very improperly so; it ought of course to be called *pneumato-thorax*. *Pneumo-thorax* means something about lung and chest, but *pneumato-thorax* means something about air and chest. We have such a word as *pneumatocele*, signifying a swelling produced by air; and when air exists in the thorax we ought to say *pneumato-thorax*, because *πνευμα* is the Greek for air, and according to common analogy we should change the genitive into *το*. We say *hæmatocele*, we do not say *hæmocene*; therefore Laennec is wrong in the name which he has given to the disease, which consists of air existing in the pleura. This is unimportant, and one is not disposed to dwell upon words, only when a new term is invented it is right to make it legitimate according to other words. With words that have been long established we must be contented, and not be over nice.

Symptoms.—Now when air exists in the pleura, it of course gives rise to the same effects of distention that the existence of pus or serum does; the intercostal muscles swell out a little, and the diaphragm and liver, in the case of the right side, are pushed down. But you may beforehand predict what will be the signs to the ear.

There will not be a dead sound, as in the case of the effusion of pus or serum, but on striking the chest you will have a hollow sound, though on listening to the chest you will, as in hydrothorax, have no respiratory murmur. The air that is there is not the air of respiration, but exists external to the lungs, and therefore it does not give any respiratory murmur; but there is this great difference, that if you strike the chest, notwithstanding there is no more respiratory murmur than in the abdomen, yet you have a fine clear hollow sound.

You see, in this instance, the importance of not trusting either to percussion or to the stethoscope separately; you see that a case may occur in which the combined use of percussion and auscultation is necessary. If you merely strike the chest in these instances, you see nothing the matter, for it gives a fine hollow sound—perhaps a clearer sound than in health: and again, if you only listen to the chest, without striking—merely apply the stethoscope—you will say, here is a lung solidified, or here is a pleura filled with liquid, with pus, or serum. But by using both, you see clearly the nature of the case; you ascertain, by the fine hollow sound, that air is there, but by the want of respiratory murmur you perceive that the air has nothing to do with the lungs.

Symptoms.—When air exists in the pleura, you have, as I have just observed, a clear sound on percussion, which would lead you to suppose that all was right; but clear as the sound is, there is no respiratory murmur at all. I instanced this as a proof of the propriety of not trusting simply to the stethoscope, nor simply to percussion; and it is an excellent instance of the propriety of having recourse to both.

You will recollect, that when I spoke of a collection of liquid in the pleura, I mentioned that, however large the collection might be, you would still hear respiration about three fingers' breadth from the side

of the spine; that the roots of the lungs were never so compressed but that you might hear respiration there; although, in extreme inflammation of the lung, the lung becomes so solid that no respiration can be heard. Now it is exactly the same when the pleura becomes distended with air. When the lung is compressed by air in the pleura, still the compression is never such that respiration cannot be heard at the roots of the lungs—at least it must be an extremely rare occurrence. The lung still resists sufficiently to maintain its function at the roots, and consequently, at the sides of the spine you may hear the respiratory murmur.

Diagnosis from Emphysema.—There is one case in which the auscultatory phenomena resemble those which are noticed in pneumato-thorax, and that is one that I have already mentioned under the head of chronic bronchitis, when the air-cells are greatly distended, and perhaps broken one into another. When the disease improperly called “emphysema of the lungs” takes place (I say improperly, because emphysema is the existence of air in the cellular membrane, and in this case it is contained in the air-cells of the lungs), there is a great cavity in the lungs filled with air; and you will recollect I mentioned that there is a very clear sound on percussion, but on listening to the respiratory murmur you scarcely hear any thing. The cases, in their nature, you perceive are very similar—that is, cases where air exists in the pleura, and cases where some of the air-cells are very much enlarged and partly broken down, so that a body of air exists in the substance of the lungs and is nearly stagnant, does not pass and repass as it ought to do in respiration. There is, however, a mode of distinguishing between the two cases, and it is this: when air exists in the pleura, you hear no respiratory murmur at all at the front of the chest—it is stagnant; but in the case of dilatation of the air-cells, the air, although nearly stagnant, is never quite so—it is partially expired and inspired—and therefore you do hear a faint respiratory murmur. Another mode of making the diagnosis is this: when the case is one of dilatation of the air-cells, it is consequent upon a long-continued catarrh, or bronchitic affection; it only takes place when a disease has existed a long time, and you hear the mucous, sonorous, and sibilous rattles of bronchitis, so that you may very clearly altogether make out the nature of the case; whereas, when air exists in the pleura, it is, for the most part, a very sudden affection, there are no signs of bronchitis; and it is not only sudden, but generally very violent, and usually confines the patient to his bed.

Hydro-Pneumato-Thorax.

A compound case sometimes happens; one made up of the two affections of which I have last spoken—of hydro-thorax, or empyema, from the fluid existing in the pleura, and pneumato-thorax, in which air exists in the pleura. We sometimes see patients with both air and fluid in the cavity of the pleura.

This affection is termed *hydro-pneumato-thorax*. It is a long word, but very expressive; it shews you at once the nature of the case—hydro-thorax, the name for fluid, and pneumato-thorax, the name for air in the chest. There is nothing puzzling in the term, although it is a long one.

Symptoms.—If you reflect a moment, you may, as in many other cases of affection of the chest, predict before-hand what will be the symptoms of this disease perceptible by the ear. The air, of course, must be at the upper part of the chest, unless there be adhesions there, and the fluid will be at the lower; and therefore, on percussion at the superior part, you have a clearer sound than natural, but when you strike at the inferior part there is a dead sound. The contrast is very great indeed; the sound above is clearer than usual, whereas the sound below is perfectly dead. If you listen with the stethoscope during respiration, to all parts of the side of the chest, you hear no respiratory murmur; the air above and the fluid below impedes respiration, and therefore there is no respiratory murmur either in the one situation or the other. But there is this difference between simple hydro-thorax and pneumato-thorax—in the former case there is a dead sound from the presence of the fluid, in the latter there is a clearer sound than natural from the presence of the air; and in a compound case there is a dead sound below and a clear sound above. And again: you will be aware, that if you alter the position of the patient, you alter the situation of these phenomena. If the patient under examination be sitting or standing upright, the symptoms will be what I have stated; but suppose you make him lie down, you will then find that the hollow sound, instead of being at the superior part of the chest, will be altogether at the anterior, and the dead sound on percussion will be quite by the side; just as you alter the relative position of the air and the fluid.

There is, however, in this case (and that, I think, you might imagine) another circumstance which takes place only in this disease—viz. that if you suddenly shake the patient, take him by the shoulder and jolt him, you frequently hear fluctuation. You cannot hear fluctuation in emphysema alone, nor can you hear it in hydrothorax;

neither is it audible where air only exists in the chest: it is only perceptible in hydro-pneumato-thorax. You may hear the fluctuation with the naked ear applied to the chest, or by means of the stethoscope. It is well, in all cases of this sort, to put the ear on the patient's chest, and let some one move him rather suddenly; and then you will hear fluctuation within, and the patient will be aware of it himself. Sometimes the patient has discovered this before the medical attendant has thought of the nature of the case. You will find a very remarkable case in one of the volumes of the Dublin Transactions, which occurred before Laennec's time. The patient did not say, like the woman in Scripture, that he had spent all his substance on physicians, but he had been to all the doctors within his reach, and moreover he had been sent to the Continent, but it was all in vain; nobody knew the nature of his malady, and he discovered it at last himself. He found that when he was sitting up, or jolted himself in any way, he heard fluctuation within his chest; he pointed the attention of his medical attendant to it, who then, for the first time, listened to his chest. Now this phenomenon is mentioned by Hippocrates, or in some of the works ascribed to him, but unfortunately it is there said that it takes place only when pus exists in the chest. This is incorrect; it takes place only when there is both liquid and air in the chest, the reason of which is, of course, very evident. Those who attended to what Hippocrates or the writer of this passage said, endeavoured to verify it by dissections; but found that the observation was inaccurate, and therefore it dropped to the ground, and medical men neglected to apply the ear to the chest (although Hippocrates had done so), and stigmatized the plan as being mere nonsense. Unfortunately the observation was not sufficiently minute; the sound was ascribed solely to the existence of pus, and so the mistake was made.

Metallic Tinkling — There is another symptom (for which you would not be prepared) which exists when there are these compound contents (air and fluid) in the pleura; and that is, *metallic tinkling*. It is exactly like the sound which, according to Laennec's description, is made by striking a pin against a piece of glass. It is a clear, silvery, ringing sound—a sort of metallic sound, as is implied in the expression *metallic tinkling*—a very beautiful sound. It was long after I began to study the auricular symptoms of diseases of the chest, before I heard this; and till I did hear it I mistook many a one for it. There is a click in some diseases of the chest, which I for a long time mistook for it, and which all people will do when they

are first studying it. When, however, I once heard the real sound, the difference was so great that it prevented me running the chance of mistaking it again. You will hear a click, but it is not fine and silvery; but in the real metallic tinkling the sound is very much like that which is made by wetting the finger and rubbing it upon a glass vessel. It is not so loud, but it is a fine, clear, expansive sound.

This sound may be heard most frequently by putting your ear to the patient's chest, and then raising him, or causing him to be raised, suddenly upright. It is supposed that then a portion of pus drops from the upper part of the chest down below, and thus produces the sound. At any rate, the way I have stated is one of the best modes of hearing it. You may hear it by this means when you cannot hear it in any other mode; but in one particular case of air existing in the pleura, you will hear it when the patient is speaking, coughing, or even breathing; and that case is where the air has got into the pleura through the lungs. The air, I shall presently mention, sometimes, it appears, may be secreted in the pleura, sometimes it is the result of a decomposition of puriform fluid, but sometimes it enters the pleura through a rupture of the surface of the lung. If a communication be established between the lung and the pleura, whether by ulceration of a tubercle, by rupture, by gangrene of the surface of the lung, or by a wound, then you will have this clear silvery sound when the patient is speaking—perhaps when he is coughing, or perhaps when he is breathing. An aperture of this description most frequently takes place from an abscess of the lung—from a tubercle bursting; so that there is both air and pus effused into the cavity together; and in this case there is always a clear metallic tinkling. I believe I mentioned that in the patient whose lungs I shewed you a few weeks ago there was a most beautiful metallic sound. On striking the chest when I first saw him, I found a perfectly dead sound all over the lower part of the chest; and being told that it was a case of consumption, of course I did not know the reason of it. But on listening above, I found no respiratory murmur, and the nature of the case, in my estimation, was then clear. When he spoke, there was a fine, clear, ringing sound all over the chest; and when he coughed, it was exactly the same. After a time, it entirely disappeared; and then I presume that a small cavity which had existed in the lung, forming a communication between the lung and the pleura, had healed. In about a fortnight there was no ringing sound to be heard, and the patient, after going into the country, was

apparently a great deal better. After a time, when I saw him again, there was still no respiration to be heard over nearly the whole of the chest, and there was a dead sound on percussion, not merely at the inferior but at the superior part of the thorax. There was no more metallic tinkling, and it was clear that what had been filled with air was now filled with fluid only. An operation was performed, and a quantity let out day after day, till it amounted to many quarts—gallons, I believe. I forget how much was evacuated, but it was an immense quantity: unfortunately, however, there was too much other disease for the operation to cure him.

Amphoric Buzzing.—When air exists in the pleura, in consequence of such an opening as I have now described, before the silvery sound is heard you will occasionally hear a particular sound from air going in and out of the opening; and it is so much like the sound which you make when blowing air into a bottle, that it has been called *amphoric buzzing*. I do not recollect ever having heard it.

Diagnosis from Abscess of the Lung.—I just now mentioned that when the air cells are dilated, and a cavity exists in the lungs filled with air, the symptoms in some measure resemble those arising from air existing in the pleura, because the one is a great cavity, and so is the other. Now if it so happen that a great cavity exist in the lung, filled half by pus and half by air, the circumstance is very much the same as when the occurrence takes place in the pleura. Just as a cavity in a large dilated air cell resembles the cavity in the pleura, and gives rise to nearly the same symptoms, so a large abscess in the lung, filled half with air and half with fluid, resembles the pleura when in the same condition; and you will therefore have the same phenomena—that is to say, metallic tinkling. If the symptoms take place from a large abscess existing in the lungs, containing both air and fluid, on raising the patient suddenly a drop will descend from the upper to the lower part, and cause a silvery sound. But if the case be not very clear, it can be made out from this circumstance—that you will have, when a cavity exists in the lungs, pectoriloquy, or the air going through the tube, as if the person's mouth were at the other end of the stethoscope; whereas, in cases where the pleura is affected, as there is no great communication between that and the bronchial tubes, you do not have this phenomenon; and where an abscess in the lung, containing partly air and partly fluid, is large, it will give you a sense of fluctuation upon suddenly shaking the patient.

Cause of Pneumato thorax.—Now with re-

spect to the cause of pneumato-thorax, it far more frequently than not takes place suddenly, and I believe it more frequently happens than not to phthisical patients, in whom unfortunately a tubercle has existed close to the surface of the lung, and nature has not formed an adhesion of the surface of the lung to the costal pleura, so that ulceration has gone on to the pulmonary pleura, which has become thin, till at last it has ulcerated through. This has frequently happened when a patient labouring under phthisis has made a violent effort, and rupture has taken place.

General Symptoms.—The general symptoms, then, are extreme dyspnoea; and a person who does not use his ear might perhaps be led to suppose that it was merely an attack of inflammation, especially if the patient had been running out of doors in the evening. One might then suppose that the patient had caught a violent cold, and he might be bled and blistered all to no purpose, the nature of the case simply being, that air had escaped into the pleura. The importance of listening to the chest in such a case is self-evident; for you may make out the nature of the case clearly enough by striking the chest; you find a perfectly clear sound, and yet on listening to the respiration you hear no respiratory murmur.

Treatment.—Under such circumstances an operation should be performed; the parts should be punctured and the air let out. You will find an interesting case of this description described in one of the medical journals three or four years back, which occurred to Dr. James Johnson. It occurred to a medical practitioner who ran to a case of midwifery, and was seized with difficulty of breathing and the symptoms I have just mentioned. Several practitioners were called in, one of whom said that he had had a similar case the preceding winter, and that the patient was cured with hyoseyamus; but nobody had the least idea of the true nature of the affection except Dr. J. Johnson, and he was so satisfied respecting it, that I think Mr. Guthrie, at his request, made an opening in the chest, and out came a rush of air, and the patient felt immediate relief. This was a great object effected—at least all those who have been in pain know what a blessing it is to get half an hour's ease. The patient died afterwards, because he was phthisical; but had there been no other disease than this accidental escape of air, no doubt he would have done well. I believe I mentioned that if it occur on the left side of the chest it will push the heart to the right side, just the same as a collection of fluid. Of course the operation would not be required merely because you hear air in the chest; it need only be performed where

there is such difficulty of breathing as to make it necessary to do something for the relief of the patient. So in a compound case, one of hydro-pneumato-thorax, where there is both air and water in the chest, no operation would be required unless there was extreme dyspnoea. It is best to make the opening large enough to let out the liquid, so that, after the air has escaped, the fluid may be evacuated.

The general treatment would be that of phthisis, or a large abscess—supporting the strength, &c. These are rare cases comparatively, but it is very necessary to know them. You every now and then in practice will meet with such a case; and if you know the nature of it, although you may not be able to cure the patient yet you may do him great good; you may lessen his sufferings, and sometimes you may even cure him. When air exists in the pleura merely from gangrene of the lung at that spot, and the separation of the eschar, a circumstance which will occur when the gangrene is quite partial, the operation in such a case might be followed by complete success. If air were disengaged merely from a quantity of fetid pus underneath, it is possible then that the operation might be the means of saving the patient's life, by putting an end to the dyspnoea, which would perhaps have killed him, and then the other disease may be made to subside. Phthisis is rarely cured, but these other affections sometimes are; it may happen, therefore, except the patient have phthisis, that the disease may be permanently cured.

TUBERCULAR DISEASE OF THE PLEURA.

There are certain other diseases of the pleura of an organic nature, upon which I will not detain you above a few minutes. Occasionally the same disease attacks the pleura which forms phthisis when it exists in the lungs. The pleura is in a state, though not very frequently, of tubercular deposit. Sometimes in phthisis you will see one pleura, or both, beset with tubercles of various sizes, generally small, but sometimes of a large size.

Symptoms.—The deposition of tubercles in the pleura may be attended with scarcely any symptoms whatever, because phthisis may exist at the same time, and the symptoms of the greater disease may swallow up those of the small one. But sometimes, if the disease exist alone and is of any amount, there will be all the signs of a pleuritic effusion into the chest—all those symptoms which I just now mentioned, and it may not be easy to make a diagnosis in a case of this description. One is continually surprised on making a post-mortem examination, to find tubercles in

the pleura. But if the disease be considerable in any one spot, you will have marks of pleuritis; inflammation will take place around the tubercle, and suppuration will occur; but it is not easy to distinguish inflammation from such a source as that, from inflammation of a simple nature.

When suppuration takes place, pus may be discharged into the pleura, or without suppuration there may be an effusion from excessive secretion into that cavity, and the secretion may be serous or purulent—in fact, you may have pleuritis, and all the consequences of pleuritis, so that you may have air pass in, and all those other changes will take place which I mentioned as occurring without tubercles, and the patient will become hectic.

Treatment.—The treatment of the case will depend entirely upon the presence of air, the presence of fluid, the presence of signs of inflammation, and so on. It is only necessary to know, that all the changes which I have now mentioned are sometimes connected with tubercles in the pleura itself, and that sometimes very minute tubercles will exist there, and give rise to scarcely any symptoms at all; tubercles are frequently observed there when they are seen in various other parts of the body.

Perhaps more frequently than not, when pleuritis is chronic, when the patient has a fixed pain in the pleura of an inflammatory nature, and wastes away, it is a scrofulous affection, and is attended by this tubercular deposition. The tubercles most probably are situated in the cellular texture, immediately under the serous membrane.

Ossification of the Pleura.—I have seen the pleura ossified to a great extent; and here again it is not the pleura, properly speaking, that is ossified, at least originally, but the cellular membrane under it. The cellular membrane is frequently converted into bone in various parts of the body, or bony deposit takes place in the cellular membrane; perhaps that is a more accurate mode of speaking. But the pleura above the bone will sometimes disappear, waste away, so that you have the bare bone on looking into the cavity of the pleura. I recollect once meeting with this occurrence to a great extent in an old man who died of ascites and liver disease, and who was not aware that he had disease in the pleura—at least he never attracted our attention to it. I recollect remarking how well he could lie down notwithstanding the fluid in his belly, and I found the pleura covering several ribs in a state of ossification.

Schirrhous and Melanoid disease of the Pleura.—Other affections may occur in this situation; you may have schirrhous and melanoid disease, but these are comparatively rare affections.

DISEASES OF THE HEART.

ACUTE PERICARDITIS.

The subject to which I now pass will be inflammation and organic diseases of the other serous membrane contained in the chest—inflammation of the pericardium.

In speaking of inflammation of the pericardium, I will consider that membrane both in its loose portion, and that which is bound closely down to the substance of the heart. I believe some writers call inflammation of that portion of the pericardium which closely invests the heart *carditis*, as well as inflammation of the heart; but as it is all one continuous membrane, the loose portion and that which is bound down, and both adhere together, it is more correct to speak of inflammation of both portions under the term of pericarditis, than to call one inflammation of the pericardium, and the other carditis.

More common than was formerly supposed.—Formerly this was not supposed to be a common disease; but so far from that opinion being correct, it is an exceedingly common affection. No man in practice can pass a month without seeing cases of this description.

Supposed difficulty in making a Diagnosis.—This disease has been thought to be one not very easily made out, and like all other diseases, I suppose that sometimes it may escape the attention of good practitioners, and that they may be surprised after death to find signs of inflammation within the pericardium.

Symptoms.—The symptoms of the disease are pain in the region of the heart, and that pain is frequently increased upon pressure, provided you make the pressure between the ribs over the heart, so that it actually influences the pericardium. If you make an exceedingly great pressure upon the ribs themselves, so as to press them down as much as possible, you frequently increase the pain, and you also have an increase of pain if you push up the ends of the fingers under the cartilages of the ribs, so as to drive the diaphragm against the heart with the ends of the fingers. From that proceeding you will frequently have pain. Then the pain which is felt—not at all times, not that which you occasion merely by pressure—generally darts up to the left shoulder; it also goes through to the back, and very frequently it extends down the left arm. From these symptoms, and the increased action of the heart, together with the pyrexia which exists, I think any one would be justified in saying there was pericarditis, and if he treat it accordingly, he

will generally find himself treating the patient right.

Auscultatory Signs.—The use of the ear in this disease, so far as I have been able to notice, is rather negative than positive. I have not been able very frequently to hear any thing unusual about the sounds of action of the heart, except that the heart acts too violently. In these cases there is palpitation; but on listening you will hear nothing more than that the heart throughout is beating strongly, and perhaps all the sounds are a little increased, but not more than will occur if you make the heart beat violently from exercise, or from taking any stimulant. Now and then it will happen that the action of the heart takes place with a blowing sound, but that occurs by no means invariably: much more frequently than otherwise there is no such thing, and when it does take place, it generally continues, and the case becomes more or less chronic. It is not a necessary circumstance that it should take place, and it does not deserve, in my opinion, to be considered one of the symptoms in the disease. So frequently is this sound absent—so frequently will it arise from other causes than pericarditis—that I do not believe that if the case be one of pure pericarditis this sound will take place. I believe it only occurs when some other affection is present at the same time.

Connexion with Rheumatism.—This disease is both acute and chronic, like most other inflammations; but when it occurs in an acute form, it far more frequently than not accompanies, or has been preceded by rheumatism, and it is a disease which occurs far more commonly in young persons—in youths and young adults, than in any others. You will occasionally see it in, or after rheumatism in infants, actually in infants; but generally speaking, it attacks children perhaps from about 12 to 15 years of age, and young adults, and persons up to 30. I do not myself recollect an instance of it occurring from the suppression of rheumatism. In every case that I can recollect at this moment, it has occurred either during an attack of acute rheumatism, or some time afterwards, and not when the rheumatism has suddenly disappeared, but when it has gone slowly away, or when there has been some little degree of it still lingering in the body. I have seen rheumatism cease suddenly, and every body must, without seeing this disease as the consequence of it. It occurs far more frequently as a part of rheumatism than not, but it does not arise from the sudden cessation of that complaint in the joints. Sometimes, (and this is a curious circumstance) after the rheumatism has ceased for three or four months, when the patient

has got rid of his rheumatism entirely, a pain has come on in the side—signs of pericarditis, greater or smaller, have taken place. The French say that they consider this as the result of suppressed rheumatism in the joints, but I have never seen it. I have been in the habit of applying cold water to joints affected with rheumatism when hotter than they should be, but I have never seen this result. It will sometimes occur from cold and wet, like any other inflammation, but generally that which will produce it produces at the same time rheumatism of the joints.

First discovered by the English.—I believe it is entirely an English discovery; that this disease, or rather disease of the heart, I should say, is so connected with rheumatism. The observation was made cursorily at first. It was merely supposed that disease of the heart was connected with rheumatism. For that observation we are indebted to Dr. Pitcairn, of St. Bartholomew's hospital, but he was a diffident man, and could not be persuaded to publish it. Neither Dr. Baillie, nor any one else, could prevail upon him to make it known through the press; but he was the first person who pointed out the fact that disease of the heart was continually connected with rheumatism. Sir David Dundas, a surgeon at Richmond, subsequently published a paper on the subject in the first volume of the *Medico-Chirurgical Transactions*, but this was many years after Dr. Baillie stated the fact in his *Morbid Anatomy*, and ascribed the discovery of it to Dr. Pitcairn. Sir David Dundas, however, never makes an allusion to this, but brings it all forward with an air of novelty, and publishes it as an original discovery.

However, I think it is pretty certain that disease of the heart is not connected with rheumatism, excepting so far as the effect of pericarditis is connected with rheumatism. We every day see the latter occurrence; and whenever you see a case of disease of the heart in a young person, which has been connected with rheumatism, and the patient dies, you will find marks of preceding inflammation within the pericardium; and if you inquire into the history of the case, you will find that there were symptoms originally of pericarditis. I am quite clear that the rheumatism is connected with the inflammation of the pericardium. I will not say it produces it, because all the symptoms result perhaps from the same state of the system; but the first thing connected with the rheumatism is pericarditis, and then when that has existed any time, the organic changes of the heart take place. You may easily, I think, satisfy yourself of this by reading all the cases that have been published of diseases of the heart as consequent upon

rheumatism. You will find strong proofs of inflammation of the pericardium; and if the original history of the case be detailed, you will see strong symptoms of pericarditis. If you attend to this matter, you will find, when you inspect the body of a person who has died of the disease, marks of pericarditis; or if you make inquiry of a patient, you will find the symptoms are those indicative of the complaint, and every day, when you see cases at the onset of affection of the heart connected with rheumatism, you will see that inflammation has taken place first, and that organic disease is consequent upon that. This is a very happy circumstance, because inflammation of the pericardium may be controlled as easily as inflammation of any other part; whereas organic disease of the heart, for the most part, is an affection which we can only palliate. But it is not disease of the heart which is connected primarily with rheumatism, but pericarditis. This is nothing more than you would suppose, because young persons, who are chiefly the subjects of this disease of the heart, are not subject to organic diseases, excepting scrofula. They are subject enough to inflammation, and we know that inflammation of any part whatever will leave organic disease. The great source of organic disease is inflammation, and it is quite capable of producing every organic affection whatever—that is to say, of producing all common or structural diseases, and a predisposition to any peculiar disease. The debility produced by inflammation of another part easily makes the patient the prey of a specific affection. But it is in young subjects that this affection occurs—in young subjects who are particularly liable to inflammation of every description, and not to organic diseases of any kind, excepting scrofula.

Morbid Appearances.—After death from this disease, the anatomical appearances are just the same as after inflammation of any other serous membrane. There is sometimes redness in stars, and sometimes patches of redness. The redness seldom extends very deep, even in the most violent cases. The membrane does not become thickened, but of course a quantity of fibrin is seen lying upon it, and a quantity of serum is collected within the cavity. The fibrin is generally in very fine layers, forms layers upon the pericardium, and sometimes it lies in a mass like jelly. It is usually irregular upon its surface, having minute pores, and sometimes these pores, these little singularities, are very considerable; so that Laennec compares them to the appearance of two slabs which have had butter spread upon them, and then been forcibly separated. A number of knobs then appear, with, of course,

little excavations between them. There is often a great deal of this exudation when the redness is very considerable.

If these exudations are considerable, they will sometimes glue the two portions of the pericardium together, so that they cohere to the heart, and a cavity no longer exists, and hydrops pericardii cannot take place. Such cases have been taken as instances of the entire absence of the pericardium. There are, perhaps, half a dozen cases on record where no pericardium existed; but there is no question now that the cases so described are altogether doubtful: they were nothing more than instances of the cohesion of the two portions of the pericardium—the loose, and that which immediately invests the heart; so that a mistake has been committed. You find, in one of these instances, that there had been a complete cohesion; but occasionally the adhesion is partial—exists here and there. Of course there is a very great variety as to the strength of these adhesions; sometimes they are very slight, like those in the pleura, and sometimes they are very tough, fleshy, indeed almost cartilaginous. In regard to the quantity of fluid which is produced from the inflammation, it is seldom very considerable: now and then it is, but that is a rare occurrence. For the most part, the fluid presents the same appearance as in other inflamed serous membranes. Sometimes it is turbid, of a yellow colour, containing a few flakes of lymph; but now and then, as in the case of the pleura, it has the appearance of pus, and even absolute pus has been found in a large quantity, and that within the pericardium. Dr. Baillie says that he once saw a quart of pus in the pericardium, and no ulceration existed: it was pus secreted by a serous membrane, exactly as you frequently see it secreted by a mucous membrane.

Treatment.—As to the treatment of the disease, when it is acute there is nothing peculiar in it, and I will not take up your time for a moment in speaking of it. The treatment is the same as that for active inflammation in any other part of the body, only it is to be remembered that this inflammation is seldom violently active—it is generally moderate inflammation, and disposed to become chronic. When acute inflammation is not very intense, the best way of attempting to remedy it is by local bleeding; and a very moderate inflammation of the pericardium, just like a moderate inflammation of the pleura or the peritoneum, is best treated in that way. I think, in my own practice, I have noticed that pericarditis yields more readily to free local than general bleeding; and I believe this is owing to the general princi-

ple that inflammation, when, although it is acute, nevertheless is not very intense, is best remedied by local means.

Now inflammation of the pericardium, when acute, is seldom of a very active character—not so active as pleuritis or peritonitis; and it is disposed to fall into the chronic form. I believe the greater number of persons who have pericarditis do not die of it immediately, but at a remote period; and then death arises from acute inflammation degenerating into the chronic form. This is the principal danger arising from pericarditis. Mercury should be given, rest should be enjoined, and the patient should be restricted to low diet. These are the only observations that I think it necessary to make respecting this affection: nothing more can be said than what I have advanced over and over again, respecting the treatment of inflammation in general.

GULSTONIAN LECTURES, 1833.

ON THE FUNCTIONS OF THE ABDOMEN, AND SOME OF THE *Diagnostic Marks of its Disease.*

BY RICHARD BRIGHT, M.D. F.R.S. &c.

[Continued from page 287.]

HAVING, then, cursorily called to mind a few of the various functions dependent upon the viscera of the abdomen, let us consider the causes which chiefly derange these functions.

The morbid conditions of the viscera may be, in a great degree, referred to the following general heads:—Excessive action, natural in its kind, very generally depending on irritation, either direct or sympathetic;—defective action, natural in its kind, often accompanied with, and sometimes originating in, a state of congestion;—perverted action;—simple inflammation;—malignant action;—scrofula;—ossification. And the numerous morbid appearances may be chiefly referred, in the same way, to temporary increased vascularity from irritation, either local or sympathetic, or from congestion or overloaded vessels;—increase of natural structure;—decrease of natural structure;—alteration of structure, depending on perverted action, on scrofula, on common and on malignant inflammation.

First, then, I say that excess of action, natural in its kind, very generally depending on inflammation either direct or sym-

pathetic, is to be considered an important source of disease.

Here I am well aware that I am employing two words of which it might be difficult for me to furnish concise definitions, but I must beg leave to use them according to the conventional language of our profession; by irritation, intending to express an undue excitement chiefly exercised upon the extreme distribution of the nerves and capillaries; and by the term sympathetic, referring to those actions of an organ, or part, which depend upon actions going on primarily in some other organ or part, and in general to be traced to some obvious or believed communication through the medium of the nerves. And it may be well to pause a moment, that we may realize to ourselves the nature of those organs respecting which we speak—that we may feel convinced as to their capability of being affected by such actions—that we may inwardly admit the probability of their being under the influence of such remote agencies. View here a portion of injected intestine—view here the vessels of a secreting gland. Mark here the tubes which convey that fluid whose course was pointed out to us by HARVEY, whom we delight to call our own. See how nature has ordained that the streams of life, the stimulus of healthful action, the means of nutriment, the source of secretion, shall be borne in its silent and unobtrusive way through every particle of our frame. Grant, now, for one moment, that its healthful balmy nature be changed into a direful poison; or grant that the particles on which it acts be each turned but one atom from its accustomed bearings; and then venture to predict what will be the result of myriads of agencies, now no longer healthful, when multiplied by the quick beat of the fevered heart. Shall we not now willingly confess the probability that slight morbid actions, such as the mild term of irritation would almost seem to exaggerate, may produce great effects upon organs thus constituted?

Look, again, at the nervous system: see how the fibres communicate and interlace; observe how all have direct relation to the brain—the great organ on which the modification of our thoughts and feelings, in some mysterious manner, seems to depend; and acknowledge, in these fine threads, a clue which, if carefully followed, will lead us, in part at least, through the labyrinth of those associated actions to which we properly apply the term of sympathetic.

It is by no means difficult to find examples of simple excess of action going on in the abdomen; as, for instance, the increased action of the intestines from various articles of food, or from remedies . .

or the increased action of the kidneys, from mild diuretics. These I advance as instances of simple increased action by causes directly influencing the organ; and while I say this, I am desirous of modifying the expression; for as, in all probability, every remedy we use has some peculiar mode of action, we cannot strictly assert that what it produces is but the natural action; it may, however, be so nearly that which is natural that the secretion resulting may be in every important respect the same as in health; and the supposed diversity of action, therefore, may fairly be left out of the account.

As instances of action increased by sympathy, may be cited the disturbance of the bowels, depending on mental emotion, and the profuse secretion of the kidney in hysteria. We have defective, though natural action, in cases of habitual constipation and in the sluggish action of the liver, often so effectually and speedily relieved by simply exciting the system and relieving the circulation by exercise, by purging, or by local depletion.

We recognize perverted action, without any signs of inflammation, in many cases where the secretion of the stomach becomes acid or morbidly changed—in the reversed muscular action of the stomach producing vomiting, or of the duodenum throwing bile into the stomach—in the altered secretion of the kidneys under the various calculous diatheses—and still more in diabetes.

It is not always easy to draw the line between the simple excess or defect of natural action and the state of inflammation; for it cannot be doubted that very often an increase or a diminution in the function of any organ is a prominent symptom of inflammatory action: still, however, there is an essential difference between these states. In inflammation there is always something superadded to the natural action, beyond a mere deviation in its degree or intensity: an impulse, or a mode of action essentially new, is introduced, frequently attended with constitutional excitement, betraying itself by the character of the pulse, and tending not only to increase or to diminish the customary action and secretion of the vessels of the part, but to alter their action, and ultimately to produce fixed results which approach each other, whatever the organ affected may be, although these results suffer modifications from the nature of the action properly belonging to the part affected.

Thus, as I have just observed, the activity of the kidney, as regards its function, may be increased or diminished so as to produce the most remarkable deviations in the quantity of urine secreted;

or its action may be so perverted that new combinations may be produced, and ingredients altogether foreign to the natural fluid may be generated: yet there may be no one plea from pyrexial effort in the constitution, from the state of the pulse, from local sensation, or from any other admitted symptom, to pronounce the existence of inflammation. The same may be said of the liver—the same of the intestines; and when submitted to the most careful examination after death, not even increased vascularity may be traced, and no evidence may be discoverable of those results which genuine inflammation always tends to produce; no accumulated serum—nothing like adhesive process—nothing like the deposit of lymph—no tendency to the secretion of pus, nor any signs of suppurative or gangrenous disorganization. We cannot, therefore, with any propriety, consider these actions, however excessive or however changed they may be, as inflammatory, unless we wish to confound all action under one common term.

When simple inflammatory action exists, for a certain period proportioned to the severity of the action and the nature of the part, nothing beyond functional change is induced, and the vessels are capable of resuming their natural state. In the progress of this morbid action, however, either serum or fibrin is thrown out; but even when this is the case, if the inflammation be speedily subdued these substances are capable of being absorbed, so that the parts may return very nearly to their natural state. Should the inflammatory action be still more severe, or still more protracted, organic changes of a most marked kind take place, to an extent defying the action of the absorbents; and it is fortunate when the powers of organization can reach these effused substances, so that they may become incorporated, as it were, with the healthy parts; for then, though they may in some degree impede the functions of the organ, they are less likely to set up fatal irritation, or produce suppuration in important structures.—The organized results of inflammation shew themselves in adhesions, in the opacity of membranes, and in the thickening of organs by interstitial deposit; and very beautiful it is, in some cases where inflammatory action has produced effusion, to observe the progress of vascular organization, the fine filamentous union, first without marks of vessels, then gradually injected by vessels which seem like the returning bending of the capillaries, pushed forwards into the newly-created nidus, and distended by the additional impulse, till they carry red instead of colourless particles; and these

bow-like vessels advancing till the membranous substance becomes completely organized.—But when the powers of absorption or of organization cannot influence the substances which are thrown out, we find permanent effusion produced, either of solid or of fluid matters, which produces irritation, renewed inflammation, and suppuration; or, as the effects of the primary inflammation, we may have the suppurative process, ulcerative absorption or gangrene, produced: and again, as the result of inflammation, we occasionally find the balance of the nutritive and absorbent vessels destroyed, and natural structure absorbed.

There is a species of morbid action which is so universal in its influence, and so little confined to any one set of organs, or, as far as we yet know, to any particular tissue or structure, that it is necessary to advert to it as a separate morbid influence; and that is what we style **MALIGNANT** action. There appear to be several modifications of this influence, marked by varieties in the changes they induce, and which are sufficiently distinct in their most characteristic forms, but occasionally run into each other so as to be completely mixed and confounded. The three most distinct varieties are the scirrhus, the fungous, and the melanotic actions. These malignant diseases are truly constitutional, but on what state of the body they depend, either chemically or pathologically, we are, as yet, quite unable to point out. It is, however, not to be disputed, that as in some individuals gout or erysipelas will succeed to even slight injury, so there are others, in whom common inflammation having been excited, the result will be malignant action; and, in some individuals, the constitution seems so completely prepared for the development of this action, that we find the marks of its agency spread most universally over the body. Not only do we discover it in external parts, but almost all the internal viscera in their turn become affected with it; sometimes communicating from part to part by the obvious course of absorption, sometimes passing from organ to organ by contiguity, and sometimes arising in various irritated parts, apparently depending on a general tendency to the disease. We are naturally led to suppose that morbid changes so marked should constantly originate in some particular tissue; and if this be the case, I should be inclined to assign the locality of its invasion to the cellular membrane connecting the firm parts of other structures. The investigations of Dr. Hodgkin, upon the subject of the anatomical structure of malignant growths, serve to shew that, in many cases at least, a regular cellular arrangement is assumed

by them, which he compares to combinations of reflected membranes, and ascribes to a peculiar power of growth arising from the diseased action. It has seemed to me probable, when considering the structures which he has so beautifully demonstrated, that the disease is first set up in the natural meshes of the cellular membrane, which is universally distributed; that the ordinary serous secretion of those minute cavities becomes changed to that more viscid character which approaches closely to the appearance of mucus, or the more firm opaque substance of the cerebriform cancer, or the sanguineous secretion of fungous hæmatodes, or the ink-like deposit of melanosis;—that this state of diseased action communicating from cell to cell, the natural cells become enlarged and their parietes thickened, gradually involving in the disease whatever structure they encounter. Thus, in parts where the cellular membrane is loose and diffused, as in the ovaries, in which there is likewise a natural tendency to form cysts, from the peculiar functions of the part, these cysts become greatly distended; where, on the contrary, the surrounding parts are less yielding, they are compressed, and where they meet with other organs, these become involved, the disease intimately pervading their structure, possibly still introduced through the medium of the cellular membrane, whose natural, almost aerial secretion, becomes changed by contiguity into the same morbid secretion, whether it be mucous, cerebriform, sanguinolent, or melanotic: certain it is, that occasionally, in examining tumors of a much milder character—even common steatomatous tumors—the same structure, or one very much resembling it, may be traced in them as in tumors of malignant growth, but the lobules of which it is composed give an impression that the cellular adipose membrane has, by a more partial and confined action, been secreting a fatty matter instead of the peculiar deposits which mark the direful march of malignant disease. When we examine even ovarian cysts, where the circumstances allow the peculiarities of growth pointed out so beautifully by Dr. Hodgkin to display themselves in all their force and variety, we often find the mucons secretion not held within decided cysts, but lodged in cavities, whose crescentic margins seem to resemble the orifices which communicate between the cells of the cellular tissue, magnified and thickened by pressure and disease: but at the same time I am inclined to believe, that while much of the structure depends for its form on the natural meshes of the cellular membrane, in many cases additional cells are formed by

newly-generated membranes; and that under other circumstances, even without the formation of such secreting cells, a peculiar vascular arrangement takes place, from which the malignant matter is rapidly deposited by numerous newly-formed vessels.

Supposing the cellular membrane to be the first point of attack of these malignant actions, we can explain their universal diffusion; while we can, to a certain degree, understand the great variety which their appearance affords, if we admit different modifications of the morbid influence. Where the secretion from the cellular membrane becomes glutinous, of a texture nearly resembling mucus, it gradually distends the cellular meshes, acting almost like an extraneous and comparatively mild fluid injected and very gradually accumulated in cavities whose parietes become thickened in proportion to the pressure they have to withstand. This glutinous secretion has little or no tendency to become organized, but remains in the form in which it is thrown out, distending the cavities in which it is received more or less, according to the structure of which they form a part. Thus we see this peculiar form of disease occasionally in various parts, as in the structure about the pylorus, in the mamma, in the glands, near Glisson's capsule, in the liver, in the kidney, but in none do we see its real nature so well developed as in the ovarian growths. It certainly at first view might appear singular that the cellular substance should not admit of a more diffused deposit of this fluid, seeing that the meshes in their natural state communicate pretty freely. This is, however, in my mind sufficiently accounted for by the nature of the fluid, and by the gradual character of the pressure, both of which tend to seal up the communication, and to distend the convex portions in such a way as rather to close than open the orifices of communication between the cells; and in point of fact we do find a very curious process often taking place in these ovarian tumors, the cell opening by a kind of process of absorption in such a way that when a portion of substance is gone, a clean, defined, and entire crescentic margin remains, looking very like the better organized portion of the original cell thus separated and left entire on the renewal of a newly deposited or feebly organized portion which has closed the orifice.

In other cases the product is of a character so totally different that were it not for the fact that the different forms of deposit are occasionally seen passing almost imperceptibly into each other, we should have great difficulty in perceiving any connexion between them. The matter which

in these cases first occupies the cell is of a more opaque colour and creamlike consistence, and is certainly more capable of organization, so that the vessels of the neighbouring parts pass into it, and divide and subdivide in most minute ramifications. This is the true medullary sarcoma of authors; and if we take a small insulated mass of this deposit, such as we often meet with in the liver, and let a fine stream of water fall upon it, we shall find a large portion of the soft matter removed, and some parts left still attached to the finely divided vessels, many amongst which will be seen carrying red blood, and giving a blood-shot appearance to particular parts.

As the substance in which the fine vascular tissue develops itself is of soft and pulpy consistence, almost like brain, but more deficient in regular organization, and still less compact and firm in its texture, the vessels are very apt to give way, and then ecchymosis, more or less extensive, to take place, and such clots and masses of red blood being mixed up with the cream-like matter, all the varieties of hæmatoid fungus will be the result.

This medullary mass has within itself a vascular structure, exerting a kind of propulsive force; and though, while in very cellular parts, as those connected with the ovaries, we find it protruding itself into successive cells, which it distends, in imitation of the mucous and glairy secretion to which I have referred, yet in more solid parts, as the liver, we rather find it pushing the neighbouring parts aside, and involving and corroding the cellular structure, which quickly ceases to present a regular appearance of rounded cells; and as the mass becomes softened and broken down, can only be traced in the form of ragged fibres pervading the medullary growth.

Melanosis appears to bear a very strong analogy to the medullary and the hæmatoid fungus in the situation of its deposit, the mode of its increase, and the nature of its structure.

The genuine scirrhus appears to occupy the same structure as the rest, but its growth is much slower, and the deposit of which it is formed is of a very different kind: it has none of that exuberance of growth which belongs to the other forms of malignant disease, but gives rise to a slow successive deposit or growth, extending along the meshes of the cellular membrane, and every part contaminated becomes opaque and hard, so that you may in some cases, particularly in the liver, watch its preference to the cellular tissue in which it pursues its course, pushing aside the acini, and often by no means assuming the same regular almost spheroidal growth which marks most of the other forms of

malignant disease. Still, however, as its progress is in all directions from every point where it is established, and there is probably a tendency in the vessels of the disease to form in diverging or radiated growths, the result is, that as the deposits enlarge, they assume a more and more spherical form.

Another morbid action as generally diffused over the system, and often scarcely less formidable in its results, though not so necessarily fatal, is that to which we give the name of scrofula. The much greater frequency of this than of malignant action, and the more decidedly hereditary character which it assumes, afford us more opportunities of observing the state of constitution with which it is connected, and has enabled us to exert a certain limited power over it, both in curing, and, what is no less important, in controlling it, and preventing its inroads. We have, however, here the same difficulty which exists with respect to other morbid actions, when we attempt to define its nature, or to point out the mode on which it influences the processes of life. We trace it in general to be connected with manifest want of power in the system, sometimes with a sluggish, dull action, in the capillary circulation, leading to congestion, but more frequently with a morbid tendency to excitement, displayed in the manners, habits, and more particularly in the personal appearance of the individual. This scrofulous action leads to most decided morbid changes in almost all the viscera of the body, and those of the abdomen participate largely in its ravages. It shews itself particularly in the absorbent glands, but is likewise discerned in the mucous apparatus, in the cellular tissue, in the muscular texture, in the solid viscera, in the serous membranes, in the bones, and in their various appended structures, and even in the recent organized products of ordinary inflammation. Its usual course is low inflammatory action, followed by deposit of matter possessed of a very inferior degree of vitality, and little, if at all, capable of becoming organized, but going gradually into a state of softening and suppuration.

The last peculiar action to which I would refer, which is a natural process, and becomes disease only as it is assumed by parts where bone is not naturally deposited, is the ossific action, which, though not very frequently recognized in the abdominal viscera, is very various in the localities it affects, and appears occasionally to be a result of secondary action consequent upon single inflammation, subdued scrofulous action, and even upon the malignant disease: thus we find bone developed in the serous membranes, in the

spleen, and even in the substance of the absorbent glands, in the coats of the vessels, and in the structure of cysts formed by morbid action, and of tumors owing their growth to scrofulous or to malignant deposit.

INSECURITY OF VACCINATION.

[The following letter has been sent us by the author, with a request for its insertion.]

To the Board of the National Vaccine Establishment.

GENTLEMEN,

IT is now upwards of twenty years since I considered that the proof of the imperfect protection obtained from the vaccine practice against the variolous contagion, had assumed such a character as to call for an immediate inquiry into the state of that discovery; and it cannot create any surprise, if, after the different steps I have judged it necessary to take, I should still continue to watch its progress, and that now, when severe cases of small-pox succeeding to vaccination are constantly occurring in great numbers through the whole of Great Britain, I should deem it requisite to address you again upon the subject.

I assure you, gentlemen, that even at the period when I first published my sentiments, it afforded me infinite regret that proof had occurred to produce such a change in my opinion of the importance of the vaccine discovery; for no medical practitioner whatever—nay, not even Dr. Jenner himself—could stand more committed, both by his declarations and his practice, for the perfect protection to be obtained from vaccination against the influence of the variolous contagion on the human body; but still I could see no sufficient reason, either from my former conduct, the votes of Parliament, or the opinions of the profession in general, to withhold stating my sentiments, when they appeared to me so decisively convincing. This was all I contended for as being necessary in 1809, and it is all I contend for still, notwithstanding the accumulated, flagrant, and distressing proof of the present day; and I cannot possibly understand how any man, or any body of men, should continue year after year to issue such meagre, garbled, and unsatisfactory reports, as are handed in by the Board to his Majesty's Government.

You, gentlemen, and the whole medical profession, who have paid attention

to the subject, must now allow that the vaccine discovery stands distinctly convicted of being an uncertain, feeble, and temporary antidote against the influence of the variolous contagion; and that not only all our fond hopes of being able to prevent the occurrence of the dreadful scourge of small-pox, but even in those who have been vaccinated, of rendering such mild and safe, must be abandoned. If this, then, is the fact, how must the individuals now feel who have placed their confidence in this practice for their protection? The very idea is distressing in the extreme; for even with the greatest care and caution they must not only stand constantly exposed to an attack of small-pox, but that attack may be of the most dangerous nature, and every relation in society placed in the most singularly distressing circumstances. From the length of time the practice has now existed, the ties of husband and wife, father, mother, and child, may be all dissolved in the most unexpected and lamentable manner; and at present, in place of resting with confidence in the protection of the vaccine practice, there is no one but must, and does, if possible, fly from the variolous disease whenever it approaches him. If this is really the state of matters, and which I aver it can distinctly be proved to be, and when now every excuse which was formerly made use of to account for the inefficacy of vaccination must be abandoned, as most frivolous and vexatious, and deserving of no attention, it is not possible to perceive the shadow of a reason why the Board, who were formed in order to watch over the public safety, and not to protect vaccination at all hazards, should abandon their duty, and not feel it imperative upon them to institute such an inquiry as shall obtain conclusions capable of satisfying the public. But if such an inquiry cannot possibly be expected to emanate from a Board who have a yearly fund of 2000*l.* for their services, the subject should be taken up by the profession in general, and more especially too by Government, who might consider saving at least 1500*l.* per annum, by reducing the grant to 500*l.*, not below their notice, when the natural consequence would be what I am contending for.

I apprehend, gentlemen, it is at the present day unnecessary either to waste your time or my own in giving any de-

tail of the proof which these averments admit of; but previous to laying before you the points which now appear to me to require our immediate attention, I beg to state, that before adopting the Jennerian practice I had *inoculated* nearly 2000 cases, and only lost two; still I did not hesitate to adopt the vaccine practice when stated to possess such advantages, and I was the third medical practitioner in Scotland who used the vaccine virus. After having vaccinated about fifty cases, and re-inoculating them, and otherwise exposing them to the influence of the variolous contagion immediately after they had been vaccinated, and finding they perfectly resisted these tests, I did not hesitate to abandon inoculation, and continued one of the most zealous and determined advocates of the Jennerian discovery, until 1808-9, when the proof occurred, which proved to my mind that it was not the antidote we all so fondly imagined, but that it would be ultimately found an *uncertain, feeble, and temporary* protection, against the influence of small-pox contagion.

Until this proof occurred I had not perused Dr. Jenner's publications upon the subject; but what was my astonishment to find that every thing therein stated not only did not contradict, but was quite in conformity to, the proof which I had met with; so much so, that if I had perused Dr. Jenner's works before adopting his practice, I should certainly have proceeded with more caution, and would have seen it somewhat in the same light with the late Dr. Alex. Monro, who, when I stated to him that I had abandoned the practice of inoculation, remarked that his opinion of the Jennerian discovery was, "that it ought to be prohibited by Act of Parliament." Although I know the Doctor was not afterwards able to resist the prodigious accumulation of proof in its favour, and became a convert to the practice, still his first declaration shewed, that as far as his acquaintance with the animal economy went, and his knowledge of the science of medicine, his impression was, that it was an experiment likely to prove complicated and unsatisfactory in its results; and it will, I am afraid, be proved, that the profession ought to have proceeded with more caution and circumspection before they placed such unlimited confidence in the discovery, for at the present moment we have very nearly arrived at the state Dr. Monro

anticipated; and unless something can be done to secure the public confidence and comfort, the practice *must really be prohibited by an Act of Parliament*.

The results, gentlemen, of vaccination, at the present moment, may be stated to be, that few or none will be found to resist the influence of variolous contagion from ten years and upwards, after having been vaccinated, if they are effectually exposed to a severe case of small-pox; or, in other words, to repeated contact with a case where there is a numerous eruption; for it is very unjust, and a great mistake, to pretend to draw an opposite conclusion, where the eruption is scanty, and the whole disease mild,—for it ought to be well known to the medical profession, that one of the methods used by the people to secure a mild disease to their children, was to bring them in contact with such mild cases, and a similar disease was generally the consequence. Now if this was found to follow, where no means of protection existed, it is not in the least surprising, where protection is in some degree obtained from the remaining vaccine influence, that a great activity of variolous contagion is required to produce any effect upon the system. Again, many of the cases of small-pox after cow-pock are so very severe as not only to propagate the disease through several children of the same family, but also to communicate it to others, producing not only many of the usual consequences of the natural disease, but even death itself, to the extent of at least 1 in 150, and all these consequences increasing in a ratio proportioned to the distance of time from the introduction of the disease.

As, gentlemen, the chief objection and doubt of the medical profession to the perfect efficacy of the vaccine disease affording complete protection against the variolous contagion, arose chiefly from its very great mildness and trifling derangement of the system, I uniformly endeavoured to produce as severe a disease as possible, and for this purpose always vaccinated in two places, only distant from each other so as that the areola of both influenced one another, being very solicitous for this purpose that both punctures should take; and to effect this, I always, if possible, used virus in its most limpid state, and taken when the areola was extensive and bright. I introduced the virus

either in its natural liquid state, or rendered it so, but as little diluted as possible. I grasped the arm in such a manner as to stretch the skin, and render it firm; I then with a lancet not very sharp introduced the virus, holding the point quite perpendicularly, dipped it into the cutis quite superficially, and proceeded moving its point backwards and forwards, as it were scratching to the extent of two or three times, so as to distil the virus into the wound, the whole vaccinated part being about the third of an inch in length. Next day I ordered a strip of fine flannel to be put round the arm, and retained there until the punctured points gave indication of active inflammation, but before the vesicles were formed: the flannel was then taken off, and if necessary, more or less extent of areola and size of vesicle was endeavoured to be obtained, by increasing the heat of the arm and body.

Although I am quite satisfied that this mode of conducting vaccination will extend its protection as far as possible, still I am convinced there is no mode of giving the disease, in the way of puncture, (what may be done by our becoming milkers, I cannot say,) that can render its effects on the human body permanent and perfect. I have met with cases of small-pox succeeding to vaccination, where four, three, two, and one puncture had been used, and the cicatrices of every appearance,—and still the length of the period of protection and the extent of the modification were the same, and of every variety; but these consequences, as I have already stated, may be very much influenced by the severity and extent of the variolous contagion to which they shall have been exposed.

What, then, gentlemen, is to be done for the public comfort and safety? I apprehend it is impossible to place any confidence in re-vaccination, although it is what has been practised by many of the profession; for, independently of the glaring absurdity of continuing to place confidence in a practice which stands convicted of insecurity, and requiring a frequent repetition, still I can venture to assert that the regular vaccine disease can never be again obtained, if the first has been satisfactorily conducted, so as to warrant the conclusion that the constitution has been a second time more or less influenced, and without that proof no additional security can possibly be conferred. It is not difficult to understand how the vaccine disease may se-

cure the human body against a repetition of its own action, but we cannot so easily comprehend how, if none of the characteristic phenomena are present, a further security can be conferred by such re-vaccination—against a disease, too, of the most virulent and opposite description, although some very zealous advocates for the perfection of the vaccine disease do not hesitate to assert that the cow-pock is even the original disease!

I would, gentlemen, dismiss this expedient as really useless and contemptible, and place our hopes of being able to continue the practice of vaccination in having recourse to *re-inoculation*. In conducting this practice, it will be found that by introducing the variolous virus from six years of age and upwards, there is nearly an equal chance of not only a regular pustule being obtained, but also feverish symptoms, and if such shall be the effect of the re-inoculation, the greatest confidence may be placed in the additional, and even perfect, security thus obtained; for surely, if we have placed confidence in vaccination in the first instance, where no distinct constitutional affection could be detected, we may place much more where such affection of the system is evident, more especially, too, when such constitutional derangement is produced by the disease we mean to oppose. But if these symptoms shall be followed with an eruption, however small in number, the most perfect confidence may be placed in the security thus conferred, and this constitutional effect, accompanied with more or less of an eruption, may be expected to follow pretty frequently, if re-inoculation is employed as a means of security, from ten years and upwards, after vaccination. No apprehension need be entertained by, or excited in, the parents in adopting this expedient, as in every instance it will very seldom be attended with much distress, and, as far as my experience goes, with no danger; for although the application of the epidemic contagion may produce dangerous effects at this period, still, when applied in the form of inoculation, the disease produced is quite mild and safe, and the consequences most satisfactory. It is very extraordinary, and much to be regretted, that there are medical gentlemen of experience and character still to be found who hesitate to recommend re-inoculation at any period from vaccination; and those who consent to such a practice still make no

distinction as to the distance of the period from vaccination; when they ought to be quite aware, that the vaccine influence gradually loses its power over the system, and, if they either advise re-inoculation at a very early period, or within six or eight years after being vaccinated, no effect at all, or at most so very trifling, that no further security and satisfaction can be imparted.

Indeed, gentlemen, the state of this question has always appeared to me somewhat different from that entertained generally, either by the profession or the public; for it is not exactly how far a greater number of lives may be saved to the community, but how any individual should feel in the after progress of life, in having the security of his existence depending upon so precarious an antidote; nor can I see clearly how parents can conceive they do their duty to their children, who out of mere feelings of ease, and distant apprehension to themselves, place their offspring in a situation that leaves them, through the whole of life, a prey to the most distressing anxiety and alarm. But even this prop is now taken away; for, as I have already mentioned, there are now more who die after placing their security in vaccination, than died when it was the practice to inoculate; and from the want of confidence in the Jennerian discovery, for many years past a great proportion of the community have used no means whatever for their protection, and great numbers actually fall a sacrifice to the variolous epidemic. In short, the whole benefits so sanguinely expected from the Jennerian practice are, at the present moment, nearly entirely forfeited.

It is this distressing result, gentlemen, that has made me now address you: I really cannot perceive the shadow of a reason for your not considering it an imperative duty to take immediate steps for arriving at such conclusions as will enable the public to feel and act in this perplexing dilemma. It is quite obvious to me that the subject should have been taken up long ago, and thereby many very distressing accidents might have been avoided: it surely neither indicates judgment, nor feeling, in so highly important a concern, only to yield to the most glaring evidence and the most disastrous facts. I certainly hold the profession guilty of all the distressing occurrences which have resulted, or may result, from no regular inquiry having been

instituted; and rather than go on floundering in such a chaos of confusion and contradiction, it would be better, both for individuals and the public in general, to give up the Jennerian discovery at once, and return to inoculation. There are not now many medical gentlemen well acquainted with what inoculation was. The extent to which the practice had attained immediately preceding the introduction of the vaccine discovery, was, that every individual who composed the rational and intelligent part of society availed themselves of its advantages, seized the opportunity of snatching their offspring from the desperate chance of one in five against their existence, at only the hazard of one in five hundred, and nearly the same chance of avoiding any other distressing consequence; and all these benefits too, notwithstanding the very astonishing, careless, and opposite treatment of the disease. I think there cannot be the least doubt, had the necessary exertions been made, that the practice would have been rendered more easy in every particular, and have become so universal as to have rendered the epidemic disease quite insignificant, if not extinct; for here a virus was taken from the disease you meant to combat—it produced one possessing all the leading features of the original: there was no dubiety about the qualities of the virus—there was no necessity for the distinction of perfect and imperfect inoculation—no uncertainty of constitutional infection—the medical practitioners were not reduced to the necessity of explaining facts, as suited the peculiarities of the case—and above all, both parents and children were for ever at rest upon the subject.

I assure you, gentlemen, no one can wish more sincerely to avoid this conclusion than I do, but still the only and best way to avoid it is—an inquiry into the present state of vaccination; and I hope and trust his Majesty's ministers will at last see the necessity of interference; for although they and all parties stand committed by the pecuniary grants of parliament, still, much greater sums have been granted with far less pretensions, and at all events can never afford any reason for persevering in so dangerous an error.

Your obedient servant,

THOMAS BROWN,

Mussleburgh.

May 21, 1833.

VACCINATION IN HOOPING-COUGH.

To the Editor of the Medical Gazette.

SIR,

SOME time ago a letter was published in your valuable journal, vol. viii. p. 46, from a correspondent, signing himself "H. M. M." on the efficacy of vaccination in arresting the progress of whooping-cough, in patients who had not been previously subjected to the former disease. Your correspondent encouraged us to hope for an account of some cases in which he successfully treated the cough by that means; and you in a note expressed a wish to receive them, in which I trust you will allow me, though so long afterwards, to join you, as they have not yet appeared.

In Dr. A. T. Thomson's interesting lecture upon whooping-cough, reported in your Gazette, vol. vii. pages 801—807, we are informed that the practice of vaccinating for the cure of the whooping-cough was first suggested in Germany, and that it is said to have been confirmed by some more recent experience in America. The doctor justly remarks that the remedy (although proved valid) must be of very limited utility, as it is not likely that vaccination should be delayed, with the risk of small-pox being taken in the interval, in order to keep it in reserve as a remedy for whooping-cough; but I am sure that he will not on that account depreciate its importance in the distressing and unusually dangerous case of *very young infants*, who occasionally suffer from the cough, and not uncommonly fall victims to its severity.

Since the publication of the letter from H. M. M., only three opportunities have occurred to me of putting to the test of experiment the power of cow-pock to arrest whooping-cough, and it succeeded in them all.

The first was the son of P. B. Esq., one of my personal friends, a child of one year, who had for some weeks been afflicted with obstinate fits of coughing, and slight spasmodic effort in the next subsequent inspirations. I requested his father to confide in me, that the infant should come to no harm, and, without giving it any medicine, to await the hoop. This child at length hooped decidedly during three or four days, so that I had no longer any doubt of the

nature of its disease. It was then vaccinated, and cured completely within the week.

The next case was an infant, under two years of age, the child of Major Fitz-M. who had very recently lost a still younger babe from the disease. The little patient had been suffering from it for two months and upwards; and neither she nor the deceased had ever been subjected to the cow-pock. He was going into Yorkshire immediately, and I advised him, as soon as he got there, to allow it to be vaccinated, which was done, and he has since informed me that the cough was completely cured by the eighth day.

My third case was a dispensary patient for fractured radius, a boy of three years old. He was brought to me about four months since, and had then been suffering from the cough for as long a period. I vaccinated him, and he ceased to hoop as the cow-pock vesicle attained its acmé; a very slight cough remaining; however, when I last saw the child, a fortnight afterwards.

Dr. Thomson particularizes the third week from the commencement of the hoop, as the proper period for vaccination: the evidence of the above cases would extend that period without limitation; but I am far from offering them as sufficient to establish more than the propriety of trying the efficacy of vaccination, in every case of whooping cough which has not been preceded by the cow-pock, or variola. My own practice is to decline vaccinating infants, unless under circumstances of exposure to the variolous infection, until they attain the age of eight or ten weeks, when the *red gum* is probably disappearing, and the process of *teething* is still to be commenced; and it is at this early age that many a life, we know not how valuable, is lost from whooping-cough—to such tender sufferers always a very formidable disease.

There is a very rare complaint, of which I have seen but two or three instances, and only one that terminated favourably. It consists of nothing else but the hoop, or a more violent spasm, producing death, without any cough preceding it. In the successful case to which I refer, the cough was produced after some months, and the child was soon cured. In the others, although they continued as long a time, no remedy appeared to be of the least avail. It would be exceedingly interesting to ascertain whether

vaccination be a cure for this frightful and most fatal disorder.

I am, sir,
Your obedient servant,
T. W. CHEVALIER.

62, Torrington-Square,
May 27, 1833.

GANGRENE OF THE LUNGS— CASE OF RECOVERY.

—

To the Editor of the Medical Gazette.

SIR,

As the following case appears to me to be rare, both as regards its occurrence and its termination, I send it for insertion in your valuable journal.

I am, sir,
Your obedient servant,
J. WYATT CRANE, M.D.

Old Cavendish-Street,
June 2, 1833.

On the 24th October, 1832, William Christie, aged 29, a saddler, living in Carrington-Street, May Fair, was admitted a patient of the St. George's and St. James's Dispensary, under my care. On going to visit him at his house, I learned that he had laboured under dyspepsia for about five years; that two years ago he suffered an attack of pleurisy, since which he had never been free from cough; that though, for the fortnight which immediately preceded his present attack, he had returned to his work, yet for the four months prior to that period he had been under medical treatment for hæmoptysis; that up to the time of his seizure he had lived very regularly, and had been exposed to no cold or moisture; and that on the evening of the 23d October, after having partaken of some light supper, which was not usual with him, he was attacked, about 11 o'clock, with violent vomiting, which, when the ingesta were discharged, consisted of a limpid fluid (not unlike the cholera rice-water), to the amount of about a wash-hand basin nearly full, before the vomiting ceased, at five in the morning. He was likewise affected with pain under the left breast, dyspnœa, and aggravation of his usual cough. A gentleman in the neighbourhood was called in, who bled him, applied a large blister in front of the chest, and administered some medicines.

On entering his room, I found him in bed, lying on his back, propped up by pillows; face congested about the forehead and eyes, from the vomiting; dyspnœa and pain in the side diminished; cough and expectoration troublesome; inability to lie on either side; bowels constipated; pulse full. I prescribed a cathartic, and put him on the use of the tartrate of antimony, beginning with gr. $\frac{1}{2}$ in \mathfrak{z} jss. of vehicle, to be taken three times a day. On the 29th he again complained of the pain in his left side, for which I ordered him a blister and increased the antim. tart. to gr. iss., taken as before. On the 31st, the symptoms having persisted, the dose was increased to gr. ij. three times a-day. This treatment was continued to the 5th November, when the tolerance of the medicine ceased; at which time a great change took place in the symptoms, a most offensive gangrenous factor being diffused through the room by the cough, breath, and sputa—which last, from their previous state of mucus, now became of a greenish-yellow purulent appearance, alternating or mixed with a reddish-brown.

The debility, which had been extreme from the first, became now more marked, and the pulse smaller and more frequent; the countenance was pale and sallow; the cough and expectoration incessant; decubitus as before, only on the back; the tongue, however, was clean and moist, and the patient had a slight appetite. The chest sounded remarkably clear on percussion, and, when measured by my friend Dr. Burke and myself, was found to be equal on both sides; but the lifting the patient upright in bed gave rise to such a prostration of strength and violent fit of coughing, that we feared he would not have rallied after it: he was therefore not again moved for auscultation or any other purpose. The stethoscope was applied to the front of the chest by Dr. Macreight, Dr. Burke, and myself; but nothing was detected, more than occasional *râle muqueux*. I do not, however, present the examination by the stethoscope (at this time first applied) as by any means a complete or accurate one; as, independently of the position of the patient,—on account of the horrible odour it was found impossible to remain for the necessary time in close proximity to him.

The symptoms now unequivocally announcing gangrene of the lungs, I felt at some loss about the fitting treatment, but prescribed a demulcent mixture, containing Oxy-mel Scillæ and Tra. Opii, with pills of Sulph. Quina, gr. j. three times a-day; regulation of the bowels, when confined; and any mild nutritious diet which he might fancy. The room, too, was fumigated with cloths dipped in a solution of chloride of lime, and hung in various parts: they were found, however, to be quite ineffectual in overcoming the odour; I therefore had saucers, containing the dry chloruret of lime, placed on the top of the bed and on the shelves at the top of the room, and an acid constantly added to disengage the chlorine. Even this, however, did not prove efficient in completely purifying the apartment—the insupportable odour was so constantly emanating from the breath, the cough, and the sputa.

On the 8th November, ung. antimonii tart. was ordered to be rubbed over the front of the chest, and on the 12th six leeches were applied, for pain under the right breast.

On the 14th December, there being no alteration in the symptoms, I omitted the mixture, continuing the pills and increasing the quantity of quinine to 2 grs. three times a-day. I also prescribed the inhalation of chlorine, 15 drops of the saturated solution, five or six times a-day. The first time this was used it created some slight irritation, in consequence of which, I combined it with Tr. Hyoscyami, which last was soon discontinued, and the quantity of the chlorine increased gradually to 30 or 40 drops. Soon after this treatment was commenced the cough became less troublesome, the odour was diminished, the reddish-brown sputa became less frequent, and the patient appeared to be a little stronger; decubitus still only on the back, and greenish-yellow sputa constantly present. The amendment of the patient now continued gradual.

On the 21st January he was enabled to lie for a short time on his left side, and to sit up a little while. The inhalation was omitted for a few days; when the sputa again becoming very offensive, and mixed with reddish-brown in small quantity, it was resumed, and the other treatment continued.

On the 15th February he was so far

recovered as to walk from his house, in Carrington-Street, to the Dispensary, in King-Street, and back; and was able to lie, without inconvenience, on his left side, though not on his right. The cough, very much diminished in frequency and violence, continued, and the matter expectorated still presented the greenish-yellow appearance, though the bad odour was now very faint. At the beginning of April he returned to his work, at which he has remained up to the present time. He is still troubled with a slight cough—not oftener, however, than four or five times in the course of the day; the character of the expectoration is quite changed, being destitute of odour, and in appearance merely mucus. He lies indifferently on either side, though more comfortably on the left than the right; has a good appetite, sleeps well, and considers himself to be in a stronger and better state of health than he has been in for two years.

Laennec states that he has seen several cases terminate favourably: he has not, however, given the particulars of any. On searching into the books in my own library, I find a favourable case quoted from the *Revue Médicale*, in Dr. Johnson's *Journal*, vol. ix. new series, p. 168; and there may be other cases on record, for I have not had an opportunity of referring to any other works than those immediately within my reach.

Since the above was written, I find, in the *Gazette des Hôpitaux*, of the 28th ult., an account of five cases of gangrene of the lungs, treated at La Pitié, by M. Le Baron Louis; two of them terminated in recovery. M. Louis considers fumigations of chlorine as one of the best means of treatment. Like many other French pathologists, he is of opinion that gangrene of the lungs is analogous to *pustule maligne*, and that it is not consecutive to inflammation. In the case which I have detailed, it appears to me to be doubtful whether the inflammatory symptoms resulted from the gangrene, or the gangrene from the inflammation: I rather incline to think that the former was the case, as the patient had been exposed to none of the causes of pneumonia or pleuritis, and the symptoms seemed rather to indicate a partial than a general inflammation.

J. W. C.

SUGGESTED AMENDMENTS OF THE APOTHECARIES' ACT.

To the Editor of the Medical Gazette.

SIR,

THAT there are defects in the Apothecaries' Act of 1815 cannot be denied, and that some alterations and additions to that Act might be made with benefit to the public is equally manifest; but the Apothecaries' Company cannot be expected, with the experience they have had of parliamentary proceedings, to introduce the subject to the consideration of the legislature. That body, in the year 1825, endeavoured, through the present Lord Chancellor (then a member of the House of Commons,) to remedy some of the defects of the Act of 1815; but their intentions, after incurring a very great expense, were defeated by a clause which was added in the House of Peers, restricting the benefits of the measure to one year. At that time the Scottish authorities attempted to procure for their graduates and licentiates the same privilege as they are now seeking to obtain—the right, namely, to practise as apothecaries in England; and although they did not accomplish their purpose, they were not altogether defeated, since it may be imagined, although it may not be said, that this restricting clause was the result of Scottish influence, and that the hope of having another opportunity of trying their luck was the secret motive for suggesting such a clause. The Company, however, grown wise by experience, and perhaps aware of the true intent of this Scottish manœuvre, have not since afforded them such an opportunity. As the subject is now again likely to be brought before parliament, I think there can be little doubt that the Company would manifest, if applied to, the same disposition to concur in amendments, as they evinced in originating the bill of 1825; and if the Act passed in that year could be revived without the limitation clause, it would remove many of the inconveniences resulting from the Act of 1815; but in order to render the measure more complete, I would suggest the following additions; namely, clauses

1. To reduce the apprenticeship from five to three years.
2. To render any person eligible to be examined who had been for three

years an articulated pupil to a physician, and who should give satisfactory proof of a sufficient medical education.

3. To render eligible for examination any doctor of medicine who had taken his degree at a university requiring a residence of not less than three years.
4. To require that every person, previously to his being bound as an apprentice, should give evidence by examination of his being sufficiently well acquainted with the Latin language.
5. To impose a certain penalty on any apothecary who should employ, as a *visiting assistant*, any person not qualified to practise as an apothecary; and to impose a certain penalty on any apothecary, or chemist and druggist, who should employ, as a compounder of medicine, any person who had not received a certificate of his qualification to act as such assistant.

If you concur with me in thinking that these suggestions would be improvements on the present state of the law, perhaps you will insert them in your journal.—I am, sir,

Your obedient servant,

AMICUS.

APOTHECARIES' REFORM — RE MARKS ON MAXILLA INFERIOR, BY MOLARIS.

To the Editor of the Medical Gazette

SIR,

Your correspondent Maxilla Inferior is an amusing person. After threatening the week before, that "he'd do, and he'd do, and he'd do"—after promising, in short, that he would "seize the lion in his den," (his very words, as I remember), he comes down on Saturday last to the combat, with a pair of *horns*, which he acknowledges to have borrowed for the occasion. Let us see what these same weapons of offence are made of,—for there is not the least danger in catching hold of them.

The horns, then, of Maxilla (always *Inferior*, as he modestly announces himself,) are presented to us in the shape of the following dilemma. The

question is about the provincial education procured under the regulations of the Society of Apothecaries, and this is the formidable reply put into the mouth of the Scotch Collèges by Maxilla:—

“Either this provincial education is better than the Scotch, or it is not. If it is better, the Scotch licentiates *will not succeed* in competition with their English rivals. If it be *not* better, it *must be worse*, and ought not to be supported by law, to the obvious detriment of the public.”

Horn 1. How know you, good master Maxilla, that men of inferior education *will not succeed*, under the new regime, in competition with men better educated? Is it so at present, as regards the medical profession? Or has it ever been so? Or is the new Apothecaries’ bill to breed a radical reform in human nature? And are the St. John Longs in future to stand upon their intrinsic merits, and be estimated by the public according to the real knowledge they possess? Why, if this be the case, there is no room for further argument about the matter: an act, sir, which *will* be followed by such desirable consequences, as your correspondent says, can want no further recommendation. But Maxilla does not see that in brandishing this assertion by way of an argument, he assumes the whole matter at issue.

Horn 2. This is the most amusing *non sequitur* I have met with for a long time. So if a thing is *not better* than another, it must be *worse*: it cannot be equally good! Because 3 is not equal to $3\frac{1}{2}$, therefore it must be less than 3! Oh, Maxilla Inferior! is this one of the weapons with which you go forth to attack the lion in his den? Have you no nails, or *teeth* (with all your *nom de guerre*)—nothing but these buckram horns to grapple with?

It is clear, sir, that Maxilla is “*sans teeth*,” or in the state of second childhood, when he has recourse to such nonsense, with a hope of supporting that side of the question which (*invitâ Minerva*) he has undertaken to advocate. His play upon the word “sufficient” (in the Apothecaries’ Act), which, after his invincible dilemma, he condescends to toss in a variety of curious ways—striking the eye with the frequent repetition of italics, is a sad exhibition of puerility. And I may add, as I have alluded to the italics, that he quotes in the beginning of his letter the following

words of the memorial to Lord Melbourne: that “their regulations have most essentially improved the schools of medicine in England, *as well as the state of medical science in general*,”—as if he meant something deep by the style of his typography. I expected, sir, to find at least the clause in italics controverted: but no,—“blessed are those who expect nothing,”—and the less, it would seem, from Maxilla *Inferior* the better.—I am, sir,

Your very humble servant,

MOLARIS.

June 3, 1833.

ANALYSES AND NOTICES OF BOOKS.

“L’Auteur se tue à allonger ce que le lecteur se tue à abrèger.”—D’ALEMBERT.

The Cyclopædia of Practical Medicine. Part XVI.

It is with much pleasure we observe that this national work is going forward cleverly and steadily. The present part contains from Paralysis to Plethora inclusive. Of the article Paralysis, we will take leave to say that it reflects upon its author, Dr. R. B. Todd, a very high degree of credit: he has treated his subject with ability, skill, and research, leaving little to be desired. Dr. Hope’s article—Pericarditis, also possesses much merit. And if we were to point out any other part of the present number specially deserving of commendation, we should lay our finger on Dr. Carswell’s—Perforation of the Viscera. By the way, we wish some less objectionable dictionary headings had been adopted, in respect to the last-mentioned and certain other articles in the work: few inquirers would dream of looking for matters here treated under the trivial titles which some of them have got. Death by lightning or drowning, for example—who would expect to find under “Persons found dead?” The probability, in this latter instance, is, that the title “Dead,” or “Death,” which would obviously have been the proper one under which to treat the various kinds of dissolution, was overlooked in the early numbers, and “Persons,” in consequence, adopted as a *pis aller*. This

ought to be rectified by a copious verbal index—which we would suggest the propriety of giving along with the last part. We have only further to remark, that not a few of the articles appear to us rather inordinately long: let the Editors exercise their prerogative of curtailment in due time, or we doubt if they will be able to bring the work to a close, as they promise, within twenty parts.

Hortus Medicus; or Figures and Descriptions of the more important Plants used in Medicine, or possessed of Poisonous Qualities; &c. &c. By GEORGE GRAVES, F.L.S. and J. D. MORRIES, M.D. Edinburgh.

THIS work, of which two fasciculi are now before us, recommends itself by the very creditable manner in which it is got up. The plates are well executed, beautifully coloured, and accompanied by letterpress in which all that seems needful for the medical inquirer is set forth. From the works of Orfila, Christison, and other eminent toxicologists, ample illustrations of the principal vegetable poisons are selected, while for the medicinal plants and their virtues a host of botanists native and foreign are quoted as authorities. If we be rightly informed, that the *Hortus* is not to exceed four fasciculi, making altogether no more than a single thin quarto volume, the compactness as well as the goodness of the work can hardly be too much praised.

The Dissector. By R. DEWEY FORSTER, Surgeon. Part I.—Accompanied by *The Demonstrator.* Part I.

THE anatomical arrangements in the *Dissector* are ingenious—but not very original; for not only does the layer-upon-layer system of Dr. Azoux's man supersede any claim which Mr. Forster might set up as to priority of invention, but we recollect having seen some years ago a work on precisely the same principle as the one before us. This we have thought it necessary to say, in consequence of a statement in the preface to the *Demonstrator*. In the *Dissector* it is intended to represent all the parts of the human body as large as life (or death rather); and the first fasciculus gives the hand and forearm, so contrived

that as we turn over the leaves we have the results of successive stages of the process of dissection. We have great doubts of the utility of all graphical works which tend to convey the notion that actual practical anatomy may be dispensed with.

MEDICAL GAZETTE.

Saturday, June 8, 1833.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

EDINBURGH SURGEONS—ENGLISH APOTHECARIES.

THE Honourable Under-secretary for the Home Department must be very much amused with the simplicity of those who imagined that their representations on the subject of the Apothecaries' Act had produced any effect upon his mind, or led him to pause in his course of legislation. Lord Melbourne, indeed, acknowledged that the subject was one beset with difficulty, and requiring much investigation; but in the face of this declaration, a bill, with a copy of which we present our readers, and we believe the very one manufactured some months ago in Edinburgh, has been brought into the House of Commons; and, before what we now write be in the hands of our readers, will probably have passed through its second stage.

The contending parties in Edinburgh and London may therefore cease to issue any more manifestoes; those of the former are not necessary, and the latter are useless: if the bill be stopped in its progress, it will be by other causes than any rhetoric which they contain. For ourselves, we object to it on several grounds: first, that it is a partial measure, not proceeding on the broad principle of the public good, but got up in a corner to serve the Scottish Colleges, and please certain parties supposed to be more in-

fluent than the English Apothecaries; and, secondly, because we fear that the correction of a particular supposed grievance is to be looked upon as an indication that no general measure of improvement in the medical profession is in contemplation. It is on this latter ground that our only hopes are founded that opposition will be offered to it on the second reading. We have heard, indeed, that the language used at the Home Office is, "let us have this Bill now, and we shall not object to a general inquiry next season:" a mode of proceeding which appears to us very like hanging a man first and trying him afterwards. Besides, is the tenure of office so little precarious that any one should run the risk of committing an injustice now, on the doubtful contingency of being able to correct it hereafter? No; if there is to be any inquiry, let *it* come first, and legislation afterwards.

That there are several things in the Apothecaries' Act which are objectionable, we have always held, and we should have been well pleased to see them amended; but in what manner the admission of members of the Edinburgh College of *Surgeons* to practise *medicine* in England is calculated to effect this desirable object, we confess ourselves unable to perceive. It appears to us, that nothing short of a parliamentary inquiry into the state of the medical profession in this country would meet the exigencies of the case, or satisfy the great body of practitioners that their interests were fully attended to, and their just claims impartially weighed. Neither can we refrain from expressing our opinion, that the Society of Apothecaries, as representing the general practitioners of England, to the number of above 10,000—and as the body through the medium of which such great and increasing improvements

have been effected in the state of medical education in this country—have not been treated with all the consideration which might have been expected; nor can we help suspecting that the government has been imbued with some tincture of that feeling which the Scottish memorialists display when they taunt their brethren in the south with deriving their subsistence from "a preposterous profusion in the prescription of drugs." This expression, as well as various others, in reference to the system of education now pursued in London, shew's how little the Edinburgh memorialists are aware of the great changes which have been for some years in progress, and how much the "general practitioner" of the present day differs from the "apothecary" of former times—for whom they appear to entertain so profound a contempt. As an illustration of their ignorance with respect to the state of education, we may allude to their remarks about the length of the London courses, which they say seldom exceed forty-five lectures. Now the fact is so far otherwise, that the most important branches of medical science occupy one continued course, from October to May inclusive, at the chief schools in London. Nor can we look upon it as any advantage possessed by the Edinburgh school, that subjects differing so prodigiously in importance and extent, as do the various branches of medicine, should, in so many instances, be treated of at the same length;—that the "institutes of medicine," for example, and the "practice of physic," should each be made to occupy the same space; to effect which the former must be extended to the most wearisome and useless minuteness, whilst the latter must be at least comparatively elliptical and defective. The essential difference between the system of education in Edinburgh and London is this: that in the former (as the above fact with regard

to the length of courses would imply) it is more abstract or theoretical; in the latter more precise and practical. The former is well calculated for men who have previously spent, or are afterwards to spend, a considerable time in hospital attendance; the latter is decidedly better adapted for those who are at once to enter upon the business of their profession. In other words, the London system sooner gives the student a practical acquaintance with disease; and this is only what might be expected from the great superiority of its hospitals. In Edinburgh there are 700 students, and one infirmary containing 250 beds: in London there are 1000 students, and numerous hospitals containing 2310 beds. In the former, the crowd renders it impossible for the student to become familiar with the disease; in the latter, the opportunities are abundant, and the field of experience ample enough for all the reapers. There is another point, too, in which the advantage in London is prodigious: we mean as regards morbid anatomy, many of the hospitals having theatres in which the causes of death are examined, and the pathological phenomena displayed in the most instructive manner. We protest, therefore, against the assumed superiority of the Edinburgh school; and we should have entered more into detail in regard to the manner in which the courses in London are conducted, had we not had occasion to enter very fully into the subject some months ago, in consequence of the learned lecturer on medicine in Gower-street having hazarded the extraordinary statement that the school to which he is attached was the only one in the metropolis at which extended courses were given on medical subjects.

From the copy of the proposed Bill, which we subjoin, we gather that it is intended to give the diplomatists of

all the universities and colleges north of the Tweed the privilege of practising in England as apothecaries; and while the Edinburgh College of Surgeons is put prominently forward, that of London is altogether excluded. The mark of the cloven foot is here indelibly stamped upon the Bill, and the place of its manufacture convincingly betrayed. But it is quite clear that the matter cannot rest here. It is not to be supposed that the London College of Surgeons will fail to claim, or can possibly be denied, privileges with regard to England which are granted to their compeers in the north; neither would it be fair to refuse to the Irish College what was conceded to all other similar institutions in the kingdom. The result of this would be the total annihilation of the Apothecaries as an independent corporation; for while we should have one set of colleges granting degrees in medicine, and another set licensing in surgery, both branches would equally constitute the holder of their diploma an apothecary; for the power of practising as such should become an appendage of the other, which he might or might not avail himself of, indeed, but which, if he desired to do so, he would not have to seek elsewhere to attain. Had this arrangement been limited to the holders of diplomas in medicine, it would have been different; but the result of applying it to licentiates in surgery would be to bring back, in its full force, the evil from which we are but just escaping—we mean that of restricting the pupil's attention to the easier and more elementary branch of the healing art—and which, as it is at the same time the more striking to the senses, would, as heretofore, constitute the alpha and omega of his studies. Corporate bodies, who do not examine and grant letters testimonial as to qualifications of the

party in regard to *medicine*, ought not, surely, to be suffered to confer licenses to practise that department of the art, to the knowledge of which, possessed by the person licensed, they do not certify! The Edinburgh College of Surgeons say of their diplomatist, only that he is "*ad artem CHIRURGICAM exercendam quam maxime paratus.*" Now we are by no means sticklers for the division between medicine and surgery being drawn with too rigid a precision; nay, we admit that the healing art is "one and indivisible;" but identity of principle and purpose, which this and similar expressions are intended to imply, by no means carry with them the idea that the subject is not very extensive—is not composed of different parts—and that a man may not be well acquainted with one of these, and ignorant of another; or, to come to particulars, that a man may not be expert at reducing a dislocation, or taking up an artery, who would be much at a loss in treating a case of hysteria or dyspepsia;—yet a young man, when he enters into practice, may probably see fifty cases of each of these, before he meets with one of the former on which to exercise his surgical skill.

But it is unnecessary to enlarge farther upon the subject; we shall either have other opportunities of reverting to it, in consequence of a Committee being appointed, or the question will have been settled by our rulers, without much reference to the merits of the question. We shall only therefore add, that if the Scotch College of *Surgeons* procure the privilege of licensing to practise *medicine* in England, it will, in our humble judgment, lead to consequences highly injurious to the present race of general practitioners, and detrimental to the interests of medical science; while, with regard to the University of Edinburgh, we must say that

they would have appeared to quite as much advantage in applying to the government to procure the admission of their medical graduates to the rank of English *physicians*, as in endeavouring to procure their recognition as *apothecaries*, and to obtain for them the right of selling medicines south of the Tweed—the only advantage which the proposed bill can confer on them.

THE GOWER-STREET HOSPITAL.

THE Reverend Mr. Wodsworth has forwarded to us some papers, and a letter, in explanation of the circumstances which led to his exertions in behalf of the North London Hospital—better known as the Gower-Street Valetudinarium. It appears by these documents that the puffing announcements about "the claims of the projected hospital"—the "ability and disinterestedness of the medical officers"—their being "some of the most able and experienced practitioners of the age," &c. &c. &c.—did not originate with himself, but were furnished to him! He only made the required statement, and observes, with regard to the professed relinquishment of fees, that "as a clergyman he could have no farther knowledge as to its practice or expediency." The only point on which he seems to have exercised his discretion related to the amount of the alleged sacrifice, which he informs us in the estimate given to him was reckoned at twelve or fifteen hundred pounds per annum!—but which he reduced to a thousand, "that he might not be guilty of exaggeration." From all this it would appear that the reverend gentleman had been misled with regard to the nature and objects of the institution, by those immediately interested in its success; and we rejoice that the remarks contained in our former article have thus afforded to one of his

sacred calling an opportunity of vindicating himself from the suspicion of having knowingly lent his pulpit in support of a job, or wilfully prostituted the cause of charity, by appealing to the benevolence of the public in behalf of a private speculation, which it is quite obvious, if carried on at all, ought to be so at the expense of those for whose profit it is intended*.

MEMORIAL OF THE LONDON PHYSICIANS.

[THE following memorial has been handed round for signature within the last few days. We are not aware of the reception which it has met with, nor whether it has actually been presented.]

The Memorial of the Physicians practising in London,

Sheweth,—That the Royal College of Physicians in London was instituted by charter, granted by Henry VIII. for the purpose of watching over the interests of medical science, and promoting the respectability of the medical profession.

That by certain by-laws framed by the College of Physicians, the right of admission into that body is confined to persons who have been educated at the universities of Oxford, Cambridge, and Dublin.

Your memorialists are humbly of opinion, that the right of admission into this corporation ought not to depend upon religious tests, but upon proof of good moral character, and adequate general and professional knowledge.

That your memorialists, who have received their education in the university of Edinburgh, or in Foreign schools celebrated for medical instruction, are subjected to the operation of by-laws, framed in opposition to their interests and professional advancement; that they are compelled to pay a considerable sum of money to a corporation with which they have no connexion, over whose funds they have no control, and with whose laws and proceedings they are quite unacquainted.

Were it required, your memorialists would have no difficulty in showing the many evils affecting the respectability of

their profession, and the advancement of medical science, which result from the narrow and exclusive system of monopoly exercised by the College of Physicians; the only conceivable consequence of which they feel persuaded is, to create jealousies and dissensions.

That your memorialists have much pain in referring to the numerous conflicts which persons, similarly circumstanced as themselves, have had to maintain against the encroachments of a corporation whose obvious interest it is to narrow the field of public competition.

Your memorialists beg to represent, that the numerous and artificial divisions in their profession are the result of the exclusive privileges conferred on the different corporations, the evils resulting from which they are most anxious to prove.

Your memorialists, therefore, humbly pray, that such general inquiry may be instituted into the state of the medical profession, as may lead to the framing of laws conducive to the interest of its members, as well as the advantage of the public.

A BILL

To amend an Act of the Fifty-fifth year of his Majesty King George the Third,

FOR BETTER REGULATING THE PRACTICE OF APOTHECARIES THROUGHOUT ENGLAND AND WALES*.

1. Whereas an Act was passed in the fifty-fifth year of the reign of his late majesty King George the Third, intituled, "An Act for better regulating the Practice of Apothecaries throughout England and Wales;"

2. And whereas by the said recited Act it is amongst other things enacted, That from and after the first day of August one thousand eight hundred and fifteen, it shall not be lawful for any person (except a person already in practice) to practise as an apothecary in any part of England or Wales, unless he shall have been examined by the Court of Examiners appointed by the Master Wardens, and Society of the Art and Mystery of Apothecaries of the City of London, or the major part of them, and have received a certificate of his being duly qualified to practise as such from the said Court of Examiners, or the major part of them, as aforesaid:

3. And whereas by the said recited Act it is further provided and enacted, That no person shall be admitted to any such examination for a certificate to practise as

* Neither are the above the only points on which Mr. Wodsworth has been misinformed: the gentleman to whom he states that he has written upon the subject, neither has, nor ever had, any connexion whatever with this journal. ED. GAZ.

* The words printed in Italics are proposed to be inserted in the Committee.

an apothecary, unless he shall have served an apprenticeship of not less than five years to an apothecary :

4. And whereas by the said recited Act it is also further enacted, That if any person (except a person then actually practising) shall, after the first day of August one thousand eight hundred and fifteen, act or practise as an apothecary in any part of England or Wales, without having obtained such certificate as aforesaid, every person so offending shall, for every such offence, forfeit and pay the sum of twenty pounds :

5. And whereas by the said recited Act it is also further enacted, That no apothecary shall be allowed to recover any charges claimed by him, in any court of law, unless such apothecary shall prove on the trial that he was in practice as an apothecary prior to or on the said first day of August one thousand eight hundred and fifteen, or that he has obtained a certificate to practise as an apothecary from the said Master Wardens, and Society of Apothecaries aforesaid :

6. And whereas another Act was passed in the sixth year of the reign of his late majesty King George the Fourth, intituled, " An Act to amend and explain an Act of the fifty-fifth year of his late majesty, for better regulating the Practice of Apothecaries throughout England and Wales," by which some of the provisions of the said first-recited Act were altered and modified ; but such last-mentioned Act had endurance only for a limited time, and the same expired on the first day of August, in the year one thousand eight hundred and twenty-six :

7. And whereas by the present regulations of the universities of Edinburgh, Glasgow, and Aberdeen, and of the Royal College of Surgeons of Edinburgh, and of the Faculty of Physicians and Surgeons of Glasgow, no person can be received on trial for the degree or diploma conferred by these bodies, who has not passed through an extensive course of professional education and study, fully qualifying him to act as an apothecary or general medical practitioner ; and a large proportion of the medicines actually prepared and dispensed in Scotland, and in the different colonies of the empire, is and has long been prepared and dispensed by persons holding such degrees or diplomas as aforesaid, without any other license or authority ; and it is therefore reasonable that every such person should be placed upon the same footing in respect to the right to practise as an apothecary or general medical practitioner in England or Wales, as any person examined and licensed by the said Company of Apothecaries is placed :

8. Be it therefore enacted, by the King's most excellent Majesty, by and with the advice and consent of the Lords spiritual and temporal, and Commons, in this present Parliament assembled, and by the authority of the same, That every person who has obtained or shall hereafter obtain the degree of Doctor of Medicine from one of the aforesaid universities, or a diploma from the Royal College of Surgeons of Edinburgh, or from the Faculty of Physicians and Surgeons of Glasgow, shall be entitled to practise as an apothecary or general medical practitioner, and to dispense medicines to his patients in any part of England or Wales, without having undergone any such examination, or received any such certificate as by the said recited Act of the fifty-fifth year of the reign of his said late Majesty King George the Third is directed, and without being liable to any penalty or disability whatsoever imposed by the said Act on any person who, not having been in practice as an apothecary prior to or on the said 1st day of August one thousand eight hundred and fifteen, shall without having been examined and received a certificate in the manner directed by the said Act, have commenced practice, or have practised as an apothecary in any part of England or Wales.

9. And be it enacted, That no such person shall be obliged, in order to recover in a court of law any charges claimed by him as an apothecary, to prove that he was an apothecary prior to or on the said 1st day of August one thousand eight hundred and fifteen, nor that he had obtained a certificate to practise as an apothecary from the said master wardens and society of apothecaries, but shall only be obliged to prove that he holds a degree of Doctor of Medicine from one of the aforesaid universities of Scotland, or a diploma from the Royal College of Surgeons of Edinburgh, or from the Faculty of Physicians and Surgeons of Glasgow, dated prior to the time at which such charges so claimed shall be alleged to have been incurred.

10. Provided always, and be it enacted, That no degree, diploma, or license, shall hereafter be conferred by any of the aforesaid universities or medical incorporations, except under the condition that previously to any candidate for such degree or diploma being admitted to examination, he shall produce evidence of having served an apprenticeship to a regularly-licensed medical practitioner keeping a laboratory for the dispensing of medicines, or of having attended for at least months at the laboratory of a surgeon or apothecary, or of an established chemist and druggist, or of a public hospital or dispensary, and of hav-

ing during that time been engaged in compounding and dispensing medicines.

11. And be it enacted and declared, That the production of a diploma under the seal of any one of the said universities of Scotland, or of the Royal College of Surgeons of Edinburgh, or of the Faculty of Physicians and Surgeons of Glasgow, shall in all courts of law and equity be and be held to be sufficient evidence that the person named in such diploma is entitled to the powers and privileges by this Act granted to any person to whom such diploma has been given, without being obliged to give further evidence in regard to the same.

12. And be it enacted, That so much of the said first-recited Act as prohibits the Society of Apothecaries from admitting any person to examination for a certificate to practise as an apothecary, unless he shall have served an apprenticeship of not less than five years to an apothecary, shall be and the same is hereby repealed: Provided always, That it shall and may be lawful for the said Society of Apothecaries to make such by-laws and regulations respecting the serving of apprenticeships by candidates for their licenses as shall appear to the said Society of Apothecaries best calculated to promote the professional instruction of such candidates.

13. "And be it further enacted, That from and after the _____ all and every person or persons who shall have received a license or licenses, certificate or certificates, of his or their fitness to practise pharmacy, or the art of an apothecary, or of his or their fitness to practise surgery, from any of the societies or incorporations within Great Britain or Ireland lawfully entitled to grant such licenses or certificates, shall and may practise as an apothecary or as a surgeon respectively, in and throughout that part of the United Kingdom of Great Britain and Ireland called Scotland; any thing in any charter, gift, or patent, now or heretofore in force in that part of the United Kingdom, to the contrary in anywise notwithstanding.

14. And whereas the surgeons and assistant-surgeons of the Royal Navy, the surgeons, assistant-surgeons, and apothecaries of his Majesty's land forces, and the surgeons and assistant-surgeons in the service of the East-India Company, do, previously to their admission into those respective services, undergo strict and perfect examination by experienced medical officers fully competent thereto, as to their sufficient knowledge and capacity in all the branches of the respective sciences and professions of surgery and pharmacy; and it is therefore unnecessary and improper that such prohibition, penalties, and dis-

abilities, which were only intended to protect his Majesty's subjects against the practice of ignorant and unskilful persons, should apply to them: be it therefore enacted, that from and after the passing of this Act, it shall be lawful for any person who has or shall have held any commission or warrant as a surgeon or assistant-surgeon in the Royal Navy, or as surgeon, assistant-surgeon, or apothecary, in any of his Majesty's land forces, or as surgeon or assistant-surgeon in the service of the East-India Company, to practise in any part of England or Wales as an apothecary, or an assistant to an apothecary, to compound and dispense medicines, without any certificate from the Court of Examiners of the said Society of Apothecaries, or any previous examination by the said Court, and without being liable to any penalty or disability whatever by reason of such practice; the said recited Act, or any other statute, law or usage to the contrary thereof notwithstanding.

ON THE FORMATION OF CALLUS,

And the Mode of Remedying it when diseased or deformed.

By BARON DUPUYTREN.

From the "Leçons Orales," published periodically, under the Baron's inspection.

THERE is perhaps no subject in pathological anatomy which has more exercised the sagacity of observers, and the imagination of those who raise up hypotheses without experience, than the theory of the formation of callus. Two opinions have chiefly prevailed in modern times—that of Duhamel, and that of Bordenave. The former attributed to the swelling of the periosteum and medullary membrane, to their prolongation from one fragment to the other, and to their ossification, the consolidation of the fracture. He held that this re-union took place, at one time by means of a simple external ferrule, at another by means of a double ferrule, one enveloping the periphery of the fragment, the other penetrating the medullary canal, where it forms a kind of wedge, of greater or less length.

Bordenave established different principles. He admits that the union and consolidation of broken bone takes place by the same mechanism as the healing of soft parts: led, without doubt, to this idea by

what happens when the fractured parts are exposed, he thought he could recognise the existence of cellular and vascular granulations between the fragments. According to him these granulations united and became solid, by the deposition of phosphate of lime in their interior. These doctrines, more or less modified, were received down to our time, when in 1808, having undertaken to verify the ideas of Bordenave and Bichat, I was astonished to find nothing which justified them. I multiplied my researches, and was led by numerous experiments to establish a theory partly founded on that of Duhamel, and which I taught in my course of pathological anatomy. Let us trace the most remarkable phenomena which we observe during the time that a fractured bone is becoming consolidated.

If the parts be examined between the first and tenth days, we find an extravasation of blood round the fragments, between them, and in the medullary canal. The ecchymosis may extend to very distant parts. Inflammation and tumefaction to a considerable extent is developed at the irritated points. The fleshy fibres become confounded with the inflamed cellular tissue, and soon cease to be distinguishable from other parts. The periosteum becomes red and swollen, is softened, and pours out a reddish serous fluid between it and the portions of bone which it covers. The medullary tissue becomes tumefied and inflamed, effacing by degrees the canal which the centre of the bone presents. The marrow becomes in some measure fleshy, and unites to that of the opposite side. If we examine what is going on with regard to the fragments, we find the clot which separates them to be absorbed in a few days, and replaced by a gelatinous secretion. From the fourth to the sixth day the surfaces of the fracture are covered with a reddish substance, of a downy appearance, but which is not always present. From the tenth to the twenty-fifth day the tumefaction of the soft parts becomes more solid; its adherence to the intermediate substance of the fragments appears every day more intimate; the muscles resume their wonted aspect and functions. The tumor, which I have called *tumeur du cal*, diminishes in extent, and separates from the surrounding parts; the tissue which composes it is homogeneous, like fibro-cartilage, and difficult to divide. If detached, it is found to consist of fibres parallel to the axis of the fractured bone. The swollen medullary membrane is transformed into fibro-cartilage, and progressively narrows the central cavity of the bone, till it finishes by wholly obliterating it.

In proportion as we advance in the examination of the formation of the callus, we observe other particulars: the process may go on to the twenty-fifth, fortieth, or even sixtieth day. In weakly subjects the work is not completed under three months. The lardaceous and fibrous mass which constitutes the "tumor of the callus," and which entirely envelopes the fragments, becomes by degrees cartilaginous. Towards the end of the time, the fragments are included in the centre of solid ferrule, which adheres to them through the whole extent of the outer surface. Externally this ferrule is covered by thickened periosteum, which passes into that covering the sound portions of the bone. The cellular tissue in the neighbourhood is still in a condensed state. The soft substance which was interposed between, in fragments, has now become more dense and more adherent to the extremities of the bone, but is yet far from uniting them in a perfect manner. The central peg continues to be prolonged towards the extremities, rapidly increases in consistence, and soon forms a very solid cylinder of bone. It is usually at this period that the apparatus is removed, but this callus is not yet to remain; consequently, I have named it the "provisional callus," to point out that nature removes it to establish other means of union between the fragments.

From the third to the fifth, even to the sixth month, the tumor of the callus becomes gradually more compact, and the central portion undergoes the same transformation. The substance between the fragments acquires all the characters and consistence of compact bone, differing only in colour. It is the transformation of this substance into bone that I have called the "definitive callus." In the concluding period of the formation of callus, the central portion becomes less dense; cells appear in its interior; it is converted into a reticular tissue, which itself finally disappears, and leaves the central canal of the bone perfectly free. The cells are then lined with a medullary membrane. After the establishment of the canal of the bone it becomes continuous with the lining membrane which secretes the marrow. The external portion of the provisional callus also finishes by disappearing. It is to be understood that the different circumstances of fractures produce some slight varieties in those which attend the callus. Thus, when the fractured bones ride, the interior portion or peg is not found, and the same happens when the bone has no medullary cavity.

To recapitulate:—The reunion of bone generally offers the following phenomena:
1. Effusion of blood and viscid fluid.
2. Ecchymosis in the cellular tissue sur-

rounding the extremities of the fracture. 3. The formation of a cartilaginous and bony ferrule externally, and of a kind of peg within. 4. Ossification of the substance interposed between the fragments. 5. Decrease of the tumor of the callus, and restoration of the medullary canal. The term of forty days, mentioned by many, is far from being sufficient; and where the fracture is oblique, or the bones ride, a much longer time is required.

This being settled, let us now state some facts to shew that at a certain period we may safely displace a bad and deformed callus. The chief question is, whether it can be done without danger? and this we shall endeavour to answer by cases well authenticated, and which have occurred under our own eyes.

CASE I.—Fracture of the Leg—Callus formed, with a deviation of the lower fragment backwards—set to rights on the fifty ninth day.

A., 44 years of age, was thrown from a horse in the street, and carried immediately to the Hôtel Dieu; he was completely drunk. Besides several bruises, and a wound on the forehead, he had both the bones of one of his legs broken. The slightest motion given to the limb threw the fragments into different directions, and imparted a distinct crepitation. The man, incapable of feeling any pain, disturbed the limb constantly, and even attempted to use it for the purpose of support; but had it not been for a deep and strong boot which he wore, he would most probably have pierced and lacerated the integuments of the leg by the fragments. Reduction could be only very imperfectly managed the first day: on the following, however, an attentive examination being made, it was ascertained that a fracture existed just at the lower third of the leg; that it was oblique from below upwards, and from before backwards; that the fragment of the tibia formed a sharp point, and had nearly come through the flesh. Placing the limb in a semiflex position, on its outer side, the fracture was reduced; compresses, and an appropriate bandage, were put on the projecting fragment; and in order to guard against the development of inflammatory accidents, two bleedings were practised; low diet, and dilute drinks, were enjoined. Much swelling, however, and pain, supervened in the course of a few days; phlyctenæ were formed on the surface; and a collection of matter was perceived at the place of the fracture, more especially on its anterior and inner part. An opening was made, and the wound dressed in the usual way. The patient, on his part, was very unmanageable, and seldom maintained the posture in which he was placed; and frequently he was so

troublesome as to require the bandage to be shifted and loosed. On the 27th day the wound was cicatrized, and appeared going on well. On the 15th there was still some swelling. Upon examining the state of the limb attentively, it was clear that consolidation had been effected, but not as well as could be wished, for there was a displacement of the lower fragment backwards. The deformity, however, was so slight, that it was not deemed worthy of being disturbed. A simple roller was put on, and the patient was allowed to move the limb and to sit up. On the fifty-ninth day, a new examination of the limb being made, whether it was that the swelling, now completely subsided, allowed a more perfect survey of the parts, or that, in consequence of some irregular motion, the limb had taken a wrong set, the deformity was now much greater than when examined last. The leg was bowed; a projection on its front at the place of the fracture, and the lower part drawn considerably backwards. This obviously required to be remedied, for walking could be but ill performed, and would only aggravate the mischief. The remedy adopted by M. Dupuytren was the application of the bandage which he has specially devised for fractures of the fibula, with deviation of the foot backwards. He tried, first, moderate reduction by handling, attempting to give a more correct form to the parts by moving the upper and lower portions in opposite directions, whilst the assistants drew the limb in the way of extension and counter-extension. He then laid along the whole of the back part of the leg a pad, shaped angularly, with its upper extremity in the ham, and its base at the heel. Over this he placed an inflexible splint of the same length, and attached the whole to the leg by several turns of a tape applied below the knee. A small pad was then put on the projection, and connected with the splint and lower cushion by several additional turns of tape. The limb was laid on its external side in the semiflex position, and no alteration of the apparel was allowed more often than every three or four days at first, but afterwards much less frequently. It remained on for twenty-eight days, at the end of which time the limb was perfectly restored to its proper form. In ten days more the patient could go on crutches, and soon after without them. Every inconvenience gradually disappeared, and the cure was complete at the end of four months from the occurrence of the fracture.

The preceding case satisfactorily disposes of the question, whether a callus may be disturbed without danger after it has existed for some time? But what length of time? This is a question in re-

plying to which a number of circumstances must be taken into account—the patient's age, his condition of body, the sort of bone affected, and the nature of the displacement. In fracture, the displacement, it is well known, may be lengthways or crossways, the former of which deserves the chief attention, for it is that which most usually occurs, and the management of which is most easy even after a long interval. It is a displacement which often arises from patients using their limbs too soon, before the callus has acquired due consolidation, or in consequence of the treatment being deficient, some one part giving way to the undue force exerted upon it; as, for example, when the limb, laid on its posterior surface, does not rest exactly horizontally, the heel being lower than the rest of the leg; or where, the limb being placed on its outer side, the patient, instead of lying on the corresponding side of his body, rests on his back, and raises his knee above the pillow. In the first case, the foot, by its weight, draws the lower fragments backwards with it, and an angular projection is made forwards at the place of the fracture. The deformity is in the reverse direction when the heel is too much raised. In the second case, the upper fragments, loaded with the weight of the leg and body, maintain a forward condition, while the lower are sunk inwards and obliquely backwards, the muscular action being ill counterbalanced.

All the circumstances being considered, and from all that we have experienced in the living body, and observed in those who have died at different periods of the consolidation of fractures, I am disposed, said M. Dupuytren, to conclude that, generally speaking, up to about the sixtieth day, it is quite possible to remodel the callus.

The methods recommended and employed for the purpose have been very numerous; but the five following may be looked upon as the principal. 1. *Rupture of the callus*, by pressure against a stick, or by striking a smart blow at the point of consolidation. Pathological anatomy has demonstrated the absurdity of this method; and what we know of the formation of the provisional callus warrants us in holding that the thing which can then be effected is not the breaking of a hard and compact body, but the new modelling a substance which is supple and elastic. 2. *Permanent extension*, with ordinary bandaging and machines for graduated extension. While the callus is still provisional, this doubtless is the most rational method. 3. *Compression*, which is principally adopted for remedying angular displacements, and is managed with splints and other mechanical agents. The utility of this plan is

confined to the earlier stages of the callus. It is the method commonly employed in Germany, with mercurial friction combined. 4. *Section of the callus*, with saw or scissors. This is the only mode of remedying a jumbled consolidation of the bones of the forearm. And, 5. *The seton*, or Weinhold's method. But what is most indispensable before any thing is attempted, is to ascertain well the nature of the displacement, and the causes which have produced and maintained it. This once known, it becomes comparatively easy to determine the direction in which the fragments must be forced, and to calculate to a degree of nicety the amount of force required. By careful manipulation, then, on the part of the surgeon and his assistants, a favourable result may be commanded.

CASE II.—*Fracture of the two Bones of the Leg, with a lateral deviation, restored on the twenty-ninth day.*

L., aged 27, after a fall from the third story of a house into the street, could neither walk nor rise. Violent pain, swelling, and ecchymosis of the left leg. Cataplasms and emollients were the only methods employed for twenty-nine days. He was then brought into the Hôtel Dieu. Upon examination, the left foot was observed to be turned outwards, and the leg to be made up of two parts joined, a little below the middle, at an angle of forty-five degrees, the apex of the angle directed inwards. Fracture and subsequent consolidation had evidently taken place. M. Dupuytren applied at once the internal lateral appareil for fractures of the fibula, acting in a direction exactly opposed to that of the displacement. The foot, projecting prominently outwards, was considerably distant from the splint, when the traction by the inferior band was begun, but in the course of the regular and steady application of the straps, the limb assumed gradually its proper form, or nearly so; for on account of the patient's murmuring at the pain, a complete reformation could not at once be effected. The leg was laid on its outer side, semiflexed; the pains became more tolerable, and the bandaging was endured. On the third day it was reapplied more tightly, a complete reduction of the parts was effected, and even a slight curvature given to the internal surface. There were no accidents up to the tenth, twentieth, or thirtieth day. On the fortieth, the appareil was taken off. The leg was solid, and of its natural form and structure. A slight swelling, however, remained about the ankle-joint. On the fifty-sixth day the patient left the hospital, and it would have been then difficult to say which of his legs it was that had

been fractured. The restored limb is fully as strong as the other one.

CASE III.—Fracture of the Radius—Displacement of the Hand in Consolidation—Reduction on the twenty-fifth day.

Mad. L., aged 69, fell one day in the street. The weight of her body came on the palm of her left hand. She felt a sharp pain in the wrist, which was presently followed by swelling; but thinking there was nothing the matter, but a simple sprain, she consulted no medical man; emollients alone were applied. She soon found, however, that her wrist was becoming more and more misshapen, and its power of motion more impeded. In consequence of this she came to the Hôtel Dieu, when an examination of the injury was instituted. The hand was found to deviate remarkably in abduction; a hollow existed at the inferior extremity of the radius; the movements of pronation and supination were extremely painful, indeed nearly impossible. M. Dupuytren perceived that there was a fracture of the lower extremity of the radius, and announced, that notwithstanding the time that had elapsed since the fracture, (twenty-five days) it was still possible to restore the limb to its natural form and functions, by modifying the callus which united the fragments. In order to accomplish this object, an assistant took hold of the forearm by its upper part, for the purpose of counter-extension; M. Dupuytren took the hand, and impressed on it a movement in a reverse direction from that of the fracture. The fragments were then seen to be carried outwards, the hollow to be filled up, and the interosseous space to be expanded. The subsequent indications were simple. Nothing more was required than to secure for the part during consolidation the modification which was now effected. The ordinary appareil for forearm fractures, with the elbow-splint, answered every purpose. No derangement occurred. The bandage was reapplied on the tenth day, and again on the twentieth. All went on well. On the thirty-second day the appareil was removed, and the patient left the hospital.

It should be observed, said M. Dupuytren, in conclusion, that the first application of the bandage should almost always be made with more force of constriction than in cases of recent fracture, and the state of the parts should be assiduously watched. If the pain be very severe, with swelling, and a diminution of feeling in the parts beyond the bandage, the appareil is too tight, and should be slackened immediately. The third or fourth day, in general, is a proper time for examining the state of things, and for applying new

efforts of reduction. As long as the deformity is not completely removed, these efforts must be made and repeated until the limb assumes its natural conformation; and it will be found, in general, that probably as much time and patience are required for attaining this object as is commonly bestowed on the treatment of a recent fracture.

LECTURES

ON THE

THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

—
DISEASES OF THE CHEST.

—
CHRONIC PERICARDITIS.

As to the chronic form of the disease, the symptoms are precisely the same as when the affection is acute, only not so violent. But in the chronic disease there are generally other symptoms, which depend altogether upon structural disease of the heart. Whenever pericarditis has become chronic, there is the greatest probability that more or less organic structural disease of the heart has taken place; and you seldom meet with a case of chronic pericarditis without observing, after death, that the valves are diseased, or the substance of the heart itself. If those adhesions take place of which I have spoken, there may be great inconvenience, or there may be none at all. I have frequently seen the two portions of the pericardium completely coherent, without any symptoms being produced; indeed I never recollect seeing a symptom that was at all referrible to them, and I do not believe that any inconvenience arises from them, though I have seen great inconvenience arise from partial adhesions: the heart appears to act just as well as when it is properly enveloped with the pericardium—as when it is in a natural state. I have never seen any symptom ascribable to it; when symptoms have manifested themselves, there has been sufficient disease to explain them, without the pericarditis. But a case came before my notice of a fe-

male who had disease of the heart, and it was a singular fact that whenever she lay on her back she was in extreme agony: she was even easier on her left side than on her back. In diseases of the heart you generally find that patients lie easier on the right side than the left, and the reason is evident,—it is because the heart is so near to the ribs; and when the patient lies on the left side there is a considerable thump against them. But this woman, though she could lie better on the right side than the left, could lie better on the left than on the back. A pain was experienced about the sternum, and she could not lie in that position. On opening the body a strong adhesion was found, so that a portion of the heart was suspended, and every time she lay on her back the heart endeavoured to drag towards the spine; but that being prevented, there was a constant stretching of the parts. I know an instance now, where the patient (a female) appears to have chronic pericarditis, and cannot lie at all on the side without experiencing a darting, stabbing, pulling sensation, on the opposite side. I have no doubt, from the symptoms, that there is an adhesion, in this case, of the side of the heart. I fancied myself that there was an adhesion in the other case in front, and, in my work on Diseases of the Heart, I have given a representation of it.

You will find in many books an account of the signs of adhesion of the heart, and almost every day I see patients who are labouring under various affections of that organ, who have been told that it was an adhesion; just as people will come with a pain of the side, and who have all sorts of fanciful notions which have been spread abroad by persons who do not dissect cases after death. I am quite satisfied that if medical men would adopt that practice they would find, as I have done, a large number of cases where there has been complete cohesion, and no reason

whatever to ascribe any of the symptoms that did occur to those adhesions. It is evident that when an adhesion of the heart is great, it must impede the heart's action; but even then, I do not believe it will give rise to palpitation. When persons come with nervous or dyspeptic palpitation, they will tell you that they have been informed there is an adhesion of the heart, and that nothing can be done for them. The fact is, that medical men entertained that opinion a generation or two ago, but it has since been abandoned: the common people, however, still retain the notion, as they usually do the opinions of their superiors, long after the latter have cast them off.

In regard, however, to effusion into the pericardium, it is a very rare thing for that to amount to such a quantity as to produce inconvenience; but still such a circumstance may occur.

The mode of discovering this occurrence would be by finding that, on striking around the region of the heart, there was a dull sound to a very great extent, and yet no signs of disease of the heart itself—no preternatural sound, as if the valves were diseased—no unusual thumping, perhaps, of the heart—no unusual loudness of the heart; and, on the other hand, no diminished sound of the heart; nothing perhaps occurring but a dulness of sound to a very great extent around the region of the heart. Still I myself never saw such a case; but those would be the symptoms which you may predict beforehand from the nature of the case; and you find them mentioned by Andral as occurring in the cases which took place in his practice. In all probability there has sometimes been a swelling of the feet, a deficiency of urine—the common symptoms of dropsy, and more or less dyspnoea. When such an occurrence takes place you may *suspect* the existence of this affection, but I do not know that you can be *sure* of it; you may suspect it, and you must treat the case accordingly.

If there be no signs of inflammation left, it will be proper to give diuretics vigorously. But we have cases on record where the pericardium has been opened under these circumstances. Of course this would be improper, unless a person appeared to be dying: unless a patient appeared to be dying from a difficulty of breathing, and fluctuation were felt, I do not think that any person would be justified in opening the pericardium, whatever were the other symptoms. When a soft fluctuating tumor has been felt about the region of the heart, you will find it said that the operation has been performed with success; but I can give you no farther information on the subject. I should like

a long consultation before I recommended the pericardium to be opened.

Transformations.

The chronic form of the disease is frequently followed by the other changes of inflammation—by the various transformations which I formerly mentioned.

Frequently the cellular membrane under the pericardium is transformed into cartilage, so that you have knobs of cartilage here and there; and sometimes you have the transformation that I spoke of subsequently to cartilaginous transformations, viz. that of bone. It is common for the sub-serous cellular membrane to become cartilaginous, and sometimes it will proceed farther, and you have bone. I have seen the heart in some instances almost encased with bone. When the heart is said to be converted into bone, I imagine the nature of the case to be this: the sub-serous cellular membrane has been ossified, and the muscular substance has wasted away. It is a common thing in various structures, when one portion becomes very hard, even to the extent of ossification, for the other constituents of the structure to waste, and that I imagine is the case in instances of ossification of the heart, as they have been called.

New Formations.

The pericardium is rarely subject to new formations; but sometimes serofulous deposit takes place in it, sometimes hydatids have been found, occasionally schirrhous, and the other new formations which I formerly mentioned.

Hæmorrhage into the Pericardium.

I believe, when speaking of hæmorrhage, I mentioned that the pericardium is a part where it suddenly takes place without a rupture of the vessels. You will find in Dr. Baillie's work an instance or two of this description. I saw the parts in a case of this kind after death, and nothing could be discovered as giving rise to this hæmorrhage; the parts were soft, that was all. I have mentioned the occurrence of cases of this kind in the stomach, intestines, and spinal canal; but it will take place in various parts of the body, without any obvious mechanical reason, and it has occurred sometimes in the case of the pericardium.

Disease of the Lining Membrane of the Heart.

I shall now proceed to speak of what may be called the corresponding membrane—the membrane within the heart. You know that the heart has a membrane within as well as a membrane without, a membrane which is continuous with the

lining membrane of the aorta and of the valves. This is subject to inflammation, the same as the pericardium is, but there are no signs by which you can ascertain its existence. You may occasionally suspect it, but it will be, I imagine, after all, a mere guess.

Morbid Appearances.—After death, however, this lining membrane is certainly found occasionally in a state of inflammation, but you are not to presume that in every instance in which you find redness of this part that there is inflammation. If it so happen that the parts are all soft, they will become dyed by the blood; they will imbibe it after death, and the blood which is in the cavity will stain them. Almost always when you find the heart softened in structure, you will observe it of a deep red colour, simply as the effect of that imbibition which I mentioned when speaking of inflammation in general, and when I pointed out the necessity of being careful in many instances not to decide that there was inflammation simply because there was redness. In the case of softness of the heart you will continually find the lining membrane of the valves and other parts intensely red, without there having been inflammation; but there is no doubt that this redness does sometimes result from inflammation. This is proved by finding fibrin effused upon the coloured portion, and adhering to it closely. Another proof is, that you find the part which is so intensely red without a drop of blood in contact with it. You will sometimes find the membrane red in particular valves, for example, and yet the whole cavity will be emptied of blood, so that it cannot be ascribed to the imbibition of blood from the part with which it was lying in contact. Occasionally this redness will arise from great dyspnoea. You are aware that when before death there is long-continued difficulty of breathing, the mucous membrane of the stomach, intestines, and bronchiæ, becomes very red, and the right side of the heart becomes gorged with blood. In these cases you will, in many instances, have redness of the inner membrane. But where a patient has died suddenly, and there has not been time for the gradual accumulation of the blood from the smaller vessels, where after death no blood is lying in contact with the red part, you sometimes find the lining membrane intensely red.

In cases of this description there has sometimes been, before death, great rapidity of the pulse, rapid action of the heart, and more or less uneasiness and smarting in the region of the heart. If this occur within the aorta, for example, there is in general great rapidity of pulse, a smarting

sensation down the spine in the course of the aorta. In the case of the heart, the only reason that you have to suppose its existence is, that in addition to the signs of pericarditis (for pericarditis is generally united with it), there is a very violent action of the heart indeed; but I confess that, more frequently than not, I have found this appearance after death without having had any reason to suspect it during life.

When the lining membrane is affected with inflammation, it is generally a mere chronic disease, just like inflammation of the pericardium; it undergoes the common changes produced by inflammation; it becomes thicker than it should be, and at the same time it becomes harder.

The parts of this membrane most frequently affected are those which form the valves. The valves, you know, are nothing more than an elongation and doubling of this lining membrane. In the case of the tricuspid and mitral valves, a portion of tendinous structure likewise enters into their composition. The chordæ tendineæ, invested as they are by the lining membrane of the heart, run along into the valves, and there are lost in the lining membrane, so that the mitral and tricuspid valves are made up of fibrous membrane and the lining membrane—tendinous and serous membrane; whereas the semilunar valves of the aorta and pulmonary artery are nothing more than the lining membrane itself protruded and extended.

Now it is a general rule observed in pathology that the lining membrane at the opening of the heart is more subject to disease than other parts, whether it be simple inflammation, or the effects of chronic inflammation in any other part. You know very well that it is not the stomach at large which is generally diseased, but one of the openings—the cardiac or the pyloric. You know that more frequently than not disease affects the intestines where the small intestines terminate in the large, or again, where the large terminate in the rectum. The rectum is the great seat of scirrhus, stricture, and various other diseases of structure. Ulcerations in fever are found more frequently at the termination of the ileum than elsewhere, and there it is we continually see scirrhus and cancer of the intestines. Instances of disease of the cardia and pylorus are infinitely more frequent than disease of the rest of the parietes of the organ. The same is observed exactly in the case of the heart, so that you have infinitely more cases of disease of the opening of the heart than you have in any other part of the lining membrane. This is nothing more than a general rule.

There is, however, another rule, which is, of course, peculiar to the heart, namely, that the left side is more subject to all diseases, and infinitely more to redness, than the right. That is a general rule, with respect both to the lining membrane within the heart and with respect to the substance of the heart itself. Various hypotheses have been formed to explain this; but the most probable explanation is, that one side of the heart receives blood of an arterial character, whereas the other has blood of a venous character. It has been thought that one side of the heart does more work than the other, but in proportion it certainly does not. Every time the left ventricle contracts, the right does the same; and so with respect to the auricles; and if the left ventricle have to send its blood farther than the right, yet the structure is much thicker than that of the right, and it is fully qualified for the exercise of the duty which it has to perform. No difference that I can discover exists between them, except that one receives arterial, and the other venous blood. Whether that will explain the circumstance I do not know; but we know, as a general rule, that arteries are more subject to all active diseases than veins; and it is very probable that the greater stimulus of the arterial blood causes other occasions of disease when applied, to act more energetically, and also causes disease to take place with more readiness.

Diseases of the Valves.

Inflammation of the pericardium, therefore, very frequently, when chronic, is united with chronic inflammation of the membrane within the heart, and most frequently with chronic inflammation of those parts that form the valves. This is one way in which organic disease of the heart is produced, viz. by pericarditis. Pericarditis seldom exists long without being followed by a similar state of the lining membrane within. You know that in the natural state these valves are quite flexible, and not transparent, but translucent; they allow light to pass through them although they will not allow you to see through them; they are fine, flexible, and translucent; but when they have become chronically inflamed, instead of being light, they become yellow; instead of being translucent, they become opaque; they lose, perhaps, their flexibility, and become more or less rigid; they play less easily, and at last become quite rigid; they lose their fineness, and become thick, and not only thick, but dense. If these changes be not very severe they give rise to no symptoms at all. If they do not

prevent the passage of blood by narrowing the opening, if they do not prevent the valve from doing its duty, no symptom that I am aware of can arise, so that you may find after death (the best auscultator in the world may find after death) disease of the valves, of which he had no idea before the patient ceased to live. It is only when function is impeded that any symptom can arise.

The change which the valves undergo will at last amount to cartilaginous hardness; they will become perfectly cartilaginous, and in a still further degree, they will become complete bone. When they undergo this change of consistency, the aperture of the part is diminished. In the case of the tricuspid valve the opening may be reduced to one-third or one-fourth; still, however, it retains generally its circular form. In the case of the corresponding valve on the opposite side—the mitral valve, the circular form is still in many instances retained, but in other cases the opening grows up in such a way that it is only a chink; instead of being circular, it is a crescent form—a semilunar sort of chink; and from the valve growing so considerably, a pouch is formed, leading from the auricle to the ventricle; so that when you open the left ventricle you see, as it were, a pouch extending nearly to it, and at the end of the pouch there may be a circular opening. Sometimes, instead of a pouch, the valve is all contracted together, and you have nothing more than a chink.

Sometimes the valves are nearly cartilaginous, and sometimes they will become bony. When there is bone it is deposited under the membrane—it is deposited, as in all cases of serous membranes, immediately under it; and then the membrane, from the presence of the bone, becomes exceedingly thin, till at last it will disappear, perhaps, over the bony portion, and the bare bone is then in contact with the blood. It is very rare for the valve to be universally converted to bone, nor is it common for it to be universally converted into cartilage, but the changes exist in different degrees at different spots, so that here and there there will be bone, and sometimes the valves will become completely cartilaginous.

In regard to the valves between the auricles and ventricles on either side, the tricuspid on the right side, and the bicuspid or mitral on the left, when they are much diseased, instead of falling back you have a very considerable curtain, and an opening, generally of an oval or circular form, in the centre of it. The different parts of the valve may become filled up, and grown up, so that you have a complete membrane between the auricle and

ventricle, and in the case of the mitral valve especially we every day see it extended in the form of a pouch. The opening in the mitral, as well as in the tricuspid valve, is generally in the centre, and circular or oval. I pointed out to you that the mitral valve is sometimes so grown up that a mere slit remains, and it is worthy of notice that this is not straight, but generally of a crescent form, in the shape of a bent finger, the concavity of the opening usually being towards the root of the aorta, and the convexity backwards. I believe the latter circumstance may be said to be universally the case. If you look from the auricle you see the light through the chink in a very remarkable manner. I believe this observation was first made by Mr. Adams, a surgeon at Dublin, who wrote a very excellent paper on diseases of the heart in the Dublin Hospital Reports. We have no specimens of the mitral valve so grown up.

With regard to disease of the other two openings of the ventricles—the opening of the right leading into the pulmonary artery, and the left leading to the aorta, disease is more frequently found in the valves of the aorta than in those of the pulmonary artery; according to the general rule, that all diseases far more frequently affect the left side of the heart than the right. It is a rare thing, indeed, for the pulmonary valves to be much diseased; but if they are, the appearances are the same as when the aortic valves are affected.

When the aortic valves are diseased, they will stand quite firm, and do not give way at all to the common pressure of the blood, so that the opening becomes diminished, and the aperture which is left in the middle of the three valves is sometimes circular, though occasionally it is triangular.

It sometimes happens that these valves are converted completely into bone—they are three shells of bone, but still they retain the appearance they present when there is only cartilage. It is very common to find bone about the aortic valves, more common than any where else, but next in frequency you find it on the mitral valve. It is sometimes found at the edge of the valve, sometimes at the bottom of the sac of the valves, and sometimes there is bone on the aorta opposite the valves. The quantity of bone is sometimes very great, and occasionally you will find it in minute granules, and not very firmly adherent, so that by rubbing it with the finger portions come off in the form of grit.

These changes are not the only ones, however, that we observe in the valves. Occasionally we find excrescences, and these are so much like venereal warts on

the genitals, that Corvisart, who has written a very good work on Diseases of the Heart, actually believed they were syphilitic. Now the appearance of warts on the genitals does not depend upon their being syphilitic, but upon their being morbid growths of a particular structure; and we know that in the greater number of cases the warts depend upon mere irritation, without any thing else.

These excrescences are very various in their appearance. Sometimes they are variously pointed, so as to exactly resemble venereal warts, and sometimes they are of a very great length. I opened a body last spring in which the excrescences were so long that they nearly reached to the apex of the heart. It was the extremest case I have ever seen. There were a number of projections from the outside of the mitral valve, but it was at the roots of the aortic valves where they were so very long.

When the valves become so changed in various ways, they frequently shrink, and become shallow, and they also shrink in breadth. They also frequently become shorter, so that the aperture is altogether diminished; and when bone is deposited upon them they frequently become brittle, and from being brittle they split and crack. The point at which the two valves unite together frequently separates, they are no longer bound down, and the two are thrown into one; and at that point the valves frequently more or less split. This is a very common occurrence. The valve is so corrugated that the division between the two is lost, and they split. This is just the same occurrence that takes place in the interior of an artery when bone is deposited there, and an aneurism arises from the deposition of bone, and not from the mere coat of the artery. Bone is deposited in the middle of an artery, and the coat splits. In the case of the heart, it is not an artery that is affected, and therefore an aneurism is not produced, but the part splits in the same way. Dr. Baillie has given an excellent representation of some of these affections.

When the aortic valves become opaque, thickened, indurated, and rugged, they sometimes corrugate, so as to curl in towards the side of the aorta, and sometimes so as to turn out. There is nothing very wonderful in all this. Sometimes they are neither curled in nor out, but remain rugged. A paper was read by a gentleman at a society announcing this as a very great discovery, but really it was no discovery at all. On looking into the work of Corvisart, which contains a mass of information on diseases of the Heart and the Aorta, and is the best you can possess, next to Laennec's on

Diseases of the Chest, I recollect he states, without announcing it as any thing important, that sometimes the valves are folded in, and sometimes they are folded out. The announcement of this as a great discovery reminds one of the man, who being asked why he turned his thumbs over each other one way, replied, he could turn them the other.

Occasionally you will find that the induration is merely at the roots of the valve: on rubbing each you will find the root semicircular and hard. These are the chief varieties of disease of the valves.

In regard to ossification, although it is seen so commonly in the aortic valves and the mitral valve, it is a very rare thing indeed to find the disease advancing so far upon the right side of the heart, but far more rare indeed to see it proceed so far upon the valves of the pulmonary artery; and the tricuspid valve of the right side is far more frequently diseased than the semilunar valves of the pulmonary artery. Thus the aortic and mitral valves are not only far more diseased than those on the right side, but, to go to the latter situation, the tricuspid valve is more frequently diseased than the valves of the pulmonary artery.

The changes to bone and cartilage, when they occur in young persons, are undoubtedly the result, in by far the largest majority of cases, of mere accidental inflammation, so that without having rheumatism, catching cold, or being exposed to the causes of inflammation, the individual would never have suffered the disease. But these affections, when they occur in old persons, I believe rarely can be traced to any particular attack of inflammation: they appear to be a degeneration of structure dependent upon age. Some parts of the body under the influence of age suffer transformations sooner than others, and this portion of the heart will become diseased in old persons really from a disposition to organic disease, and not from the result of accidental inflammation. There are instances of this change of structure which are common in various parts of the body as individuals grow older.

Although these are the parts of the lining membrane of the heart which are most frequently diseased, yet you will occasionally see the lining membrane of the ventricles and auricles, but particularly the former, thickened very much, and hardened in other parts. Sometimes the lining membrane is particularly thickened where it lines the ventricles, while at the valves it is in a healthy condition; but this is an exception to the general rule. I am not aware of any thing else worthy of being particularly mentioned as to diseases of the lining membrane of the heart.

There is, however, one little circumstance which I do not find to be much dwelt upon in books, and it is, perhaps, the result of inflammation. Occasionally, after chronic pericarditis, there will be a deposition of lymph under the mitral or tricuspid valve, which will bind it completely down, so as to prevent it from fulfilling its functions. I have myself seen several instances of this occurrence. It is just mentioned, but no more. My attention was drawn to it by Dr. James Johnson, or I should not otherwise, I think, have known any thing about it. After I had published a case of this description, I found it had been mentioned some years ago incidentally in an account of the dissection of a body; but in the regular books on diseases of the heart I do not recollect having been able to meet with any mention of the circumstance. You know that the tricuspid and mitral valves have a free floating curtain, and that if lymph be deposited between them and the heart, they may be bound down. A striking instance of the first of these affections occurred to me, and I have never met but with three or four cases. I have given a representation of the case in my work on Diseases of the Heart. One half of the valve was bound down, and the other half remained floating. That which was bound down formed a continuous surface into the ventricle. This was a case of common rheumatic inflammation: the woman had had rheumatism several times, she had had disease of the valves, and also inflammation of the left ventricle.

Now and then you will see a little ulceration of this membrane, but that is a very rare occurrence.

Effect upon the Functions of the Heart.—After having troubled you so long with these morbid appearances, we will consider what effect these changes must have upon the functions of the heart. Now the effect may be two fold;—it may be to diminish the aperture through which the blood escapes from the auricles or from the ventricles, or it may prevent the valves from doing their duty in offering an obstruction to the blood when it attempts to come back. Hence these changes may cause an obstruction to the blood going from the auricles to the ventricles, or from the ventricles to the pulmonary artery or the aorta, or prevent the valves from offering an obstruction to the blood, so that it rushes back in some degree from the ventricles to the auricles, or from the pulmonary artery or aorta into the ventricles. When the aperture is diminished, and the valves grow up, then, of course, there will be an obstruction to the transit of the blood; but very frequently the valves become so rugged that they will not distend by the

blood which attempts to return, and therefore can no longer perform the office of a valve. When the blood drives back against them, a portion of it actually does go through, but of course not the whole, because, whenever the valves are indurated and rugged, the aperture is diminished, and therefore at the same time that the diminution of the aperture prevents all the blood from going out that should do so, it prevents some from coming back that wishes to do so, and therefore there is not a complete but partial retrocession. Now the same thing will occur if the valves happen to be bound down; but I have never seen the valve bound down, except in the case of the tricuspid, and I cannot conceive it possible that it can happen in the case of the semilunar valves of the aorta or the pulmonary artery; but if the aortic valves are corrugated, and are only half their size, then they can furnish no proper obstruction, and a quantity of blood will return. Thus disease of the valves may prevent the blood from going in a natural course, or they may allow it in some measure to come backwards.

Auscultatory Signs.—These occurrences could not be known formerly in the living subject, but now that the ears are employed, they may frequently be detected during life. I presume you are aware that if you place your ear over the heart, or employ the stethoscope with one extremity placed over that organ, that you hear two sounds. The first sound which takes place is rather long, and it is immediately followed by a short sort of sound, so that you have a double sound when the heart acts. The first sound which you hear occurs at the moment of the impetus of the heart against the side, and the second immediately after it. The stroke of the heart and the first sound take place both together, and occur, if you feel the pulse at the wrist, a little before it; at least in most cases. Sometimes you cannot distinguish any interval at all between the stroke of the heart and the pulse at the wrist, but very frequently you can, and this, of course, arises from the distance of the radial artery from the heart. If you feel the artery nearer the heart, you find a less interval; if you feel the temporal artery, or the aorta itself, there is no interval at all. You may feel the aorta at the arch, and if you place one finger on that, and one on the heart, you find that the stroke at each is simultaneous; but if you place one finger on the wrist, you find there is an interval, but it is exceedingly small, and it is quite clear that the pulse at the wrist is immediately consequent on the impulse of the heart. The second sound, which takes place after the impulse of the heart, always

occurs in health after the pulse at the wrist; and the pulse of the wrist and the stroke of the heart occur so close together that in common language we may say they are simultaneous. Laennec supposed that the first sound of the heart took place from the contraction of the ventricle, and that the second occurred from the contraction of the auricle, and so he was able to predict where an obstruction would be found after death.

In regard to the nature of those sounds which occur in health, I will not describe them, because you have only to place a stethoscope, or your ear, over your friend's chest, in the region of the heart, and you will immediately perceive them. But if there be an obstruction, so that the blood cannot pass out of the left ventricle into the aorta, or from the right ventricle into the pulmonary artery, freely, then, in most instances, there is an alteration of the sound. If the mouth of the pulmonary artery or of the aorta be obstructed, a similar effect is produced to that of the arch of a bridge being narrowed, which only permits the stream to pass through it at a certain pace. The stream passing through a narrowed arch makes a whizzing sound, which was not heard before; and so if the blood, while passing from the ventricles into the pulmonary artery or the aorta, meets with an obstruction, it produces a sound not heard in health.

This sound occasionally resembles that produced by a pair of bellows, and is therefore called a *bellows sound*, or in French, *bruit de soufflet*. Occasionally it is shrill, and then it is called a *rasping sound*, or *bruit de râpe*. Sometimes it is like the action of a *fine saw*, and then it is called *bruit de scie*. It may resemble the sound of bellows, the sound of a file, or the sound of a saw. We want one word for all these sounds together, and perhaps the term *preternatural sound* would be a good generic word to embrace them. I have used it in the work on Diseases of the Heart to comprehend them all.

If the obstruction be between one of the auricles and the corresponding ventricle, then it is the second sound which is altered; and it is after the beat of the heart, after the pulse at the wrist, that you hear this preternatural sound, whether it be a bellows, a sawing, or a filing sound. There is a difference of opinion at this moment as to whether Laennec was right in ascribing the second sound to the contraction of the auricle, and I am inclined to believe that he was wrong. My reason is this:—On passing the stethoscope over the heart of a jack-ass, when the heart was laid bare, according to the experiment of Dr. Hope, I heard the second sound when the

stethoscope was placed upon the ventricle. The sound clearly came from the ventricle: and I was told by others who could see what happened, that the auricle did not contract at that time. But although I dare say the sound did not arise from the mere contraction of the auricle, yet I have no doubt that it took place at the very moment when the blood passed from the auricle into the ventricle; because, as soon as the two ventricles have contracted, they dilate, and the instant they dilate the blood must rush into them. A vacuum is formed by the dilatation, and the blood must rush out of the auricles into them, and I believe this is a passive circumstance. The contraction of the auricle appears to have little to do with it: when the ventricle dilates, the auricle empties itself; but, as far as I could observe in the experiment made, it does this in an irregular manner. However, a vacuum cannot be formed in the ventricle without the blood escaping from the auricle; and therefore I am quite sure that when there is an obstruction between the auricle and ventricle, you hear a bellows sound at the moment you should hear the second natural sound of the heart. You may form an accurate diagnosis in this way; I have done it over and over again, and have always predicted the exact part where the obstruction existed. I have always taken it for my guide that where a bellows sound was heard at the moment of the stroke of the heart against the side there was an obstruction, either at the mouth of the pulmonary artery, or at the mouth of the aorta; and, on the other hand, where a bellows sound has been heard *after* the first natural sound, that then there has always been some obstruction to the course of the blood from the auricle into the ventricle; or else the valves of the mouth of the aorta, or of the pulmonary artery, have not done their duty, so that the blood has partly rushed back into the ventricle. Whatever may be the cause of the second sound heard in the heart in health, whether the dilatation of the ventricle or not, yet it is at that moment that you hear the bellows sound, when there is an obstruction to the course of the blood from the auricle to the ventricle.

Period at which the Blood leaves the Auricles.—Laennec, as I believe I before remarked, states that at the moment of the pulse at the wrist, at the moment of the stroke of the heart against the side the blood leaves the ventricles and rushes into the pulmonary artery and the aorta, and that it is immediately after this that the blood leaves the auricle and rushes into the ventricle; so that the first sound of the heart

occurs at the moment of the stroke of the heart and the pulse at the wrist, or just before it: the difference being exceedingly minute depends upon the rush of the blood from the ventricle, and the second sound depends upon the rush of the blood into the ventricle from the auricle. Laennec, I believe, considers the first of these sounds the effect of contraction of the ventricle, and the second the effect of contraction of the auricle. It perhaps may be doubted whether, in the latter case, it arises from a contraction of the auricle, but I think there can be no doubt it takes place at the *period* he mentions, but in all probability it arises from the flow of the blood out of the one cavity into the other. It has been said that if you inspect the heart of a living animal you see that the auricle contracts before the ventricle—the reverse of what Laennec has stated. This, certainly, I have seen. But it is to be considered that the muscular part of the auricle is very inconsiderable, that the greater part is a mere venous sinus, and it must be, I imagine, when the ventricle is contracted and dilated that the blood rushes into it. Now the ventricles dilate the moment they have contracted, and therefore I should conceive that this rush of the blood from the auricle is an effect independent of the contraction of the auricle—that it is merely the effect of a vacuum produced in the ventricle by its dilatation, so that the blood rushes on as it does from the *venæ cavæ*. In the experiments I saw, the auricle contracted with all sorts of irregularity, sometimes before the ventricle, sometimes after it; and I have seen five or six contractions of the auricle to one of the ventricle, so that I do not think the ventricle is filled by the action of auricle. Another great argument is, that I have been able to make an accurate diagnosis by observing the periods of the morbid sounds as Laennec has stated them. Whenever there has been a contraction of the mouth of the aorta, or of the pulmonary artery, the preternatural sound, whether it has been a bellows, a sawing, a rasping, or a cooing sound, has been at the moment of the stroke of the heart. Whenever the trienspid, or the mitral valve, has been diseased, whenever I have seen the opening between the auricle and the ventricle on either side contracted or narrowed, then the morbid sound which I have heard has always been after the pulse—after the stroke of the heart, shewing that it is at that time that the blood leaves the auricle—that is to say, as soon as the ventricles have emptied themselves and dilated again. It so happens that within these few days a postmortem examination has been published which took place abroad.

It was the case of Dr. Hopkins, who was formerly a lecturer at Mr. Grainger's, in the Borough. It is stated here that the left ventriculo-auricular opening of the heart was ossified in its whole circumference for three lines in breadth, and that there was a singular contraction of the opening. Now it so happens that this gentleman came to me, on the 1st July, (having died, I suppose, about two months ago, for the dissection is dated February 1st) with œdema of the lower extremities and difficulty of breathing. I examined his chest, and in a moment saw signs of dreadful disease of the heart. I made pretty extensive notes of the case at the time; and founding the diagnosis on what Laennec has said, I stated there was disease of the mitral valve. I heard in that case a very extraordinary sound immediately after the stroke of the heart. It was not a bellows sound, but a variety of preternatural sounds, and sometimes there were two or three of them in rapid succession. It occurred immediately after the pulse, and was heard on the left side of the heart's region. When I listened with the naked ear, instead of this extraordinary sound it appeared like the sound of a saw. I did not doubt that he had disease of the mitral valve, or that if there were not an obstruction to the course of the blood into the ventricle from the auricle, that the aortic valves were so diseased as to let a little blood come back. I therefore wrote down in my note-book, "disease of the mitral valve, or else imperfect action of the aortic valves." Of course, if Laennec be wrong, it stands to reason that the sound I heard ought to have been heard at the moment of the heart's action. But here is a dissection taking place in a foreign country by a person who knew nothing of me or of my diagnosis, and here is the postmortem examination, and my written account of the state of the heart, corroborating each other. This shews us, as more than twenty or thirty cases have done before, that Laennec is right. He may be wrong in saying that the auricle contracts then, but I cannot consider him incorrect in saying that the blood rushes at that moment from the auricle into the ventricle. Some ascribe the sound to the circumstance of the ventricle dilating, but I am not aware that it gives a sound. I should think it more likely that it is owing to the rush of blood into the ventricle. I regretted, when Dr. Hopkins went abroad, that I should not have an opportunity of comparing the dissection with the diagnosis, and therefore I was gratified when I saw the case published.

GULSTONIAN LECTURES, 1833.

ON THE
FUNCTIONS OF THE ABDOMEN,
AND SOME OF THE
Diagnostic Marks of its Disease.

BY RICHARD BRIGHT, M.D. F.R.S. &c.

LECTURE II.

HAVING in my former lecture enumerated the chief sources of morbid change within the abdomen, I shall now enter somewhat in detail into the various symptoms which are to occupy our attention in the investigation of diseases having their seat in this portion of the body, with a view of rendering our diagnosis more complete.

And first, the countenance, the posture, and the general manner of the patient, may occasionally furnish us with some very valuable suggestions. Thus the eye is at once struck with the colour of the complexion, varying from the faintest sallowness to the most brilliant jaundice; and various deductions as to the state of the spleen, the liver, and the biliary secretions, will at once force themselves on the mind, in connexion with these facts, as I shall hereafter have occasion to point out more particularly. No less strikingly marked is the pallid, bloated, leucophlegmatic countenance, which attends certain functional diseases of the kidney, or that pale unwholesome look which, when accompanied with other corroborative symptoms, marks the existence of malignant disease within the abdomen; and equally distinctive is the shrunk and shrivelled countenance derived from long-continued disease of the stomach and alimentary canal.

The countenance often affords indications of the cause on which some symptoms depend, which are capable of being derived from various causes; for instance, if fluid has accumulated in the abdomen, the countenance may be bloated, and purple on the projections of the cheeks, the lips, and the nose, when the cause of disease lies in the heart; more completely dingy in all its parts, and darker on the lips, and darker on the conjunctiva, when the obstruction of the lungs has at length produced effusion; this purple (more particularly where the heart has been gorged) shaded with yellow in proportion as the liver has become oppressed by the retarded circulation; the complexion still more yellow where the diseased liver has acted a more primary part in causing the ascites; the countenance shrunk and furrowed

where the effusion has continued, and the viscera of the abdomen have, one by one, been involved in disease.

The countenance likewise, in acute attacks, furnishes us with much important knowledge; and although it will not be judicious to trust to its indications too implicitly, yet as corroborative of other symptoms, or as opposed to them, we daily find their importance in unravelling the complicated and contradictory symptoms with which sympathetic affections, more particularly connected with hysteria, at one time mask, and at another imitate, the spasmodic and the inflammatory diseases of the abdomen.

The posture assumed by the patient, whether in bed or sitting, often forcibly attracts the experienced eye. In peritoneal inflammation, particularly when the membrane lining the parietes is chiefly implicated, the legs are generally slightly drawn up, so as to prevent the tension of the inflamed parts. The patient prefers lying on his back; and in whatever position he finds ease, in that he remains, unwilling to risk the slightest alteration. When the pain is spasmodic the legs are often drawn up closely to the body, and the position is frequently and even forcibly changed. When disease of the heart gives rise to ascites, the semi-recumbent position will be preferred. In most cases of unnatural enlargement or tumor of the abdomen, a peculiarly restrained position of the body in walking or sitting may be observed—a kind of effort constantly made to support the unaccustomed weight, so that I have detected ascites, where concealment was the object, by this circumstance alone.

There are likewise hints to be gathered from the general manner, which are not to be overlooked:—the subdued manner of decided inflammatory disease, when contrasted with the free air of comparative health, which attends even severe neuralgic pains, or the excited, flighty, and changing aspect of the hysteric patient; the restrained movements also, which sometimes bespeak slight rheumatic affections of the joints, and thus throw light upon the nature of some inflammatory attacks on the bowels, are all subjects well worthy of attention.

The appearance of the tongue varies much in abdominal disease, but there are, undoubtedly, some pretty constant indications. In simple dyspepsia, its white and clammy surface; when dyspepsia is attended with irritation of the liver, and probably the duodenum, that white converted into a yellow fur; the red tongue of intestinal disease; the still more red, the aphthous, and excoriated surface, which it assumes in more advanced and more con-

tinued irritation of the villous membrane; the scarlet tip and edges, and the red central line bounded by a brown, an ash-coloured, or a yellow fur, in hepatic inflammation;—all these referring immediately to the disease of the abdomen, while there are others serving to point out the general condition of the system, and thus to throw light on the cause of the abdominal disease; amongst which the thick and tangible moist white crust of rheumatism, the dryer and less general white fur of inflammation, and the pallid tongue of chlorosis, may be mentioned.

The pulse is a most important symptom in this as in other classes of disease, pointing out the general fact of inflammatory action, and the progress of that action from its more violent stages, accompanied with tone and power, to its gradual subsidence in health, or its transition into sinking and collapse, either gradually, by the exhaustion of the vital powers, or more suddenly, by effusion, by rupture, or by disorganization. The full and frequent pulse, when the more solid viscera are inflamed; the quicker, the harder, and the more wiry pulse, when membranes or the intestines are implicated; the quick, sharp, irritable pulse of excessive sanguineous depletion; the rapid, the weak, the almost countless thread of arterial actions, which denotes the approach of fatal change; the uneven, irregular, and intermitting beat which indicates too surely impending dissolution. Nor must we be inattentive to the progressive stages by which these changes have been brought about, and the congruity between the indications of the pulse and the other symptoms of disease, since from these circumstances we shall sometimes derive a hint as to the degree in which nervous irritability mingles itself with inflammatory action, or even imitates its outward signs. If slight dyspepsia can so disturb the rhythm of the circulation as to lead into constant errors with regard to the condition of the heart, and if the very approach of the physician can hurry on the pulse of the hysteric female, so that it shall at once double its velocity, we must easily see how likely such causes are to influence the pulse in diseases where the stomach, the bowels, and the uterus, are all liable to be primarily or secondarily affected.

In many diseases, both chronic and acute, affecting the abdomen, the sensorium sympathizes: thus, for instance, in acute peritonitis, although we cannot consider the wandering delirium with which it is often accompanied as diagnostic, it is certainly a frequent attendant, and generally a very alarming, if not fatal, symptom. The inflammation and ulceration of the villous membrane of the bowels which take place in fever, are often attended

with a degree of delirium which has been mistaken for the result of phrenitis, though the affection of the brain or its membranes has been entirely secondary. Inflammatory congestion in the liver is often the source of temporary mental alienation, sometimes ending in insanity. In more chronic diseases, as those attended with jaundice or an undue retention or absorption of the bile, we have depression of spirits as a consequence possibly of the poison circulating through the brain. So likewise in dyspepsia, nothing is more common, and nothing more distressing, than the occasional oppression of the nervous system, and the frequent perversion of the judgment, especially with regard to things in which the patient is himself interested, leading to confirmed hypochondriasis or decided mania. Deranged functions of the kidneys influence very forcibly the sensorium; and the suppression of the urinary secretion is apt to terminate in coma and death, either from the effusion of serum, or from some unknown depressing action exerted on the brain. The uterus also excites the most powerful sympathies upon the sensorium, whose derangement evinces itself in all the varied forms of hysteria, catalepsy, hysteric epilepsy, paralysis, and hysteric mania.

On the other hand, there are certain diseases greatly affecting the alimentary canal, which are remarkably free from cerebral symptoms—as an instance of which we need only recal the composed mind and apparently unaffected condition of the brain in cholera.

A very important class of symptoms may be found in the condition of the stomach, as learnt from appreciable modifications of its action;—the state of the appetite, as it is natural, excessive, perverted, or diminished;—the existence of unnatural or perverted action, as in eructation or an approach to rumination, and in vomiting;—the time when vomiting takes place, with reference to the previous meal and the character of the matter vomited—are all important questions in forming our diagnosis;—the vomiting occurring sometimes at particular periods of the day, independently of the food taken in;—the food sometimes ejected almost immediately that it is taken in—sometimes a few minutes elapsing—sometimes the substance taken in remaining long enough to be partially digested,—all these circumstances, as well as the character of the matter thrown from the stomach, are of great importance: thus we have the insipid water of pyrosis; the acid of one kind of dyspepsia, the bitter of another; the green bile of biliary derangement; the pure blood of hæmatemesis; the grumous matter of melenæ. It

is from the comparison of symptoms like these with other connected circumstances that we come to conclusions as to the nature of the disease on which the deranged function depends; whether it be sympathy with distant organs, irritability of the organ itself, or organic derangement; and if the latter, we are led to infer the probable situation which the disease occupies in the stomach.

Another very important source of diagnostic symptoms will be found in the alvine evacuations.

When any thing like doubt or difficulty occurs in discovering the nature of disease, the practitioner is not justifiable in suffering any false delicacy to interfere with observations on the character of the alvine evacuations. It is impossible to do justice to the patient without such investigation, and it is not sufficient in many cases to take occasional opportunities, but on the contrary, the evacuations must be daily seen, and in some acute forms of disease every evacuation must be kept till the visit of the physician. In dysentery, in cholera, and in acute attacks of diarrhœa, the most important inferences, as to the daily or hourly direction of our practice, are drawn entirely from the evidence we can thus derive of the changes which have been effected upon the alimentary matter, and the derangements or gradual improvements of the secretions supplied by the various portions of the intestines and the connected viscera. There are other acute diseases, such as fever and rheumatism, in which the same attention is occasionally important; and there are many chronic diseases, such as jaundice, chronic diarrhœa, obstructions from mechanical or malignant causes, which require investigations of this kind from time to time.

Some of the various characters of the dejections are capable of description, and I have no doubt that the time will come when their indications will be more fully understood. For the most perfect formation of the healthy evacuation it is necessary that a variety of different processes should be perfectly performed. The mastication must be complete; healthy saliva must be secreted, and must be well mingled with the food before it leaves the mouth; the morsel must be swallowed with some certain degree of slowness, and it must find the stomach in a condition to receive it—not over distended with fluid—not overloaded by food already thrown into it—not fatigued by the scarcely completed processes of former digestion—not paralyzed by the actions of the mind, whether from deep thought or from anxiety—not over excited by condiments—not weakened by bodily exertion, nor suffering

debility in common with other muscular and secreting organs, from general disease or ailment, nor the subject of any partial disease within itself, or sympathetically from any other organ. When the food has been submitted to the healthy stomach it there undergoes the necessary processes, chemical and mechanical, is reduced to the almost homogeneous pulp, and it must pass forwards. If it be detained too long, here will arise another source of imperfect intestinal change; if it be allowed too quickly to pass, again the processes will be imperfect. It must find a healthy pylorus and a healthy duodenum, in which it must be mingled with a proper proportion of healthy secretions, both from the duodenum itself, the liver, and the pancreas; requiring, therefore, that the structure of those viscera should be healthy—that the vessels supplying them with blood should be healthy—that the blood itself should be healthy—that the respective excretory ducts should be pervious, and yet not allow of too rapid a flow through their orifices. The muscular action of the duodenum, as also of the whole course of the intestines, must be sufficient to produce the proper admixture of the alimentary matter and the secreted fluids, and to propel the mass in its forward course, but at the same time must be so moderate as to allow of absorption during its whole progress. The lining membrane of the intestine must be in a healthy condition, secreting a proper quantity of mucus of the healthy character, neither too tenacious nor too watery. The convolutions must not be obstructed either by morbid growths in their own structure, by spasmodic constriction of their fibres, or by causes external to themselves. The valve of the cæcum must not be constricted, nor must it suffer regurgitation. The cæcum itself must be furnished with healthy secreting apparatus—must be sufficiently capacious, and yet not so distended as to admit of, or favour, accumulation and delay. The colon must partake of the general healthy condition of the whole; its glandular apparatus must be perfect; its muscular structure vigorous; and no unnecessary delay must arise in the rectum. And when all these various parts retain their perfect condition, we still require that the absorbents should be active in taking up the nutritive portions of the food, and that the glands should fully admit its passage towards the heart. When all this, and nothing less than this occurs, we may expect to see the feculent discharge absolutely healthy.

It is highly probable that every deviation from the natural state, in any one portion of this complicated process, produces a change in the state of the evacuations; but there are difficulties in the way of our

ascertaining such facts with minute precision which are scarcely to be overcome. The circumstance that one apparatus is seldom deranged without some associated derangement, is of itself sufficient to render the investigation indefinitely complex, and the multiplicity of different ingesta serves greatly to increase the difficulty; still, however, there are particular appearances in the dejections which afford indications not to be mistaken.

In tracing the passage of the alimentary canal, there are three periods marked by very distinct changes. In the duodenum the first great change takes place; there first the bile is introduced into the mass; there first the separation of the chyle is effected. Throughout the whole tract of the small intestines a gradual alteration no doubt goes on; but along the whole passage we find a kind of imperfect mixture of mucus, of bile, and of alimentary matter, varying so much in their proportions in different parts as not to allow us to draw an exact line where any particular change constantly ensues, but from the time the matter passes the ilio-cæcal valve a most decided change is observable. There first the truly faecal character is given to the contents of the intestines, so that in the cæcum the mass may be said to undergo its second great change. As it passes along the colon this change is perfected, and in the rectum it is again changed, there assuming, as in a press, the peculiar form which distinguishes the perfectly healthy human dejection from that of any other animal; for all animals have some peculiarity in this respect; so that the game-keeper will detect the haunts of the badger, the fox, or the pole-cat, with as much facility as the common observer would see that the horse, the cow, or the sheep, had occupied a field; or the geologist would distinguish the ancient habitation of the saurian reptile from that of the antediluvian hyena.

Some of the more obvious derangements in the alvine excretions are easily detected; as, for instance, the curdled and undigested appearance marking the want of digestive power in some infantile diseases; the total absence of bile evinced in cases of jaundice from obstructed ducts, when the massive dejections are of a light drab colour, distinctly different from the white colour in some cases of chronic disease of the colon and lower part of the alimentary canal; or the light fetid loose dejections which mark ulceration of the bowels. The pale yellow produced by the defective quality of the bile in cases of hard granulated liver; the admixture of green bile and mucus when the liver has been overstimulated by mercury, or in some cases of jaundice from over-secretion of bile; the

dark olive-green of vitiated bile; the sooty dejections caused by gradual percolation of blood from the small intestines; the deep modena, or the bright red, of blood thrown off more recently and lower in the canal; the lumpy scybala formed under the defective action of the colon; the mingled blood and mucus, without a vestige of feculent character, thrown off when the membrane of that intestine is inflamed in dysentery; the clear transparent yellow water, or the opaque white fluid, which passes in cholera; the loose, yellow, gritty-looking dejection, so characteristic of the peculiar alvine irritation in the early part of some fevers; and the dark, unnatural, and unrestrained motions of the advanced and frequently fatal stages of the same disease.

There is one peculiar morbid appearance of the alvine evacuations to which my attention has lately been drawn, which is, an abundant pouring out of fatty matter uncombined with the fæces. It would appear from the observation of Berzelius, and others who have particularly devoted themselves to animal chemistry, that there is in feculent matter always a certain proportion of a peculiar fatty matter, which is mingled as a constituent part with the mass. This matter is capable of being obtained in a separate form without much difficulty; and my young friend Mr. Rees, who is ardently pursuing the subject of animal chemistry, has undertaken for me in several instances to ascertain the proportion of this substance. In general the result has been about three parts of the substance in ten of the mass, but in some cases this is decidedly increased. While, however, this peculiar substance remains mingled with the fæces, it does not offer any such very obvious characters as promise at present to be of practical importance; but under certain states of disease, this fatty matter, or a substance closely allied to it in its qualities, comes away separated, sometimes in solid round masses, and at other times like melted tallow floating on the surface of the fæces, and, on cooling, becoming concrete. Two or three cases of the former have come under my notice: in one only did a fatal event give opportunity for tracing the disease connected with this appearance, and in that the colon was extensively ulcerated. Out of four or five cases in which I have known the latter form of fatty dejection to take place, I have been present at the examination of three which have proved fatal; in all of which the head of the pancreas has been the seat of malignant disease, and the intestines (particularly the duodenum) have been more or less involved in ulceration: and on the evening I read a short communication pointing out the

coincidence to the Medical and Surgical Society, Mr. Lloyd stated a case in which the same combination of fæcal appearance during life, and of disease of the head of the pancreas and the duodenum after death, had occurred in his practice, connected with obstinate jaundice; and since that a very striking case of the same deranged state of the alvine evacuations has been published by Mr. Eastcott, in the *Medical Gazette*, where, with very defective biliary secretion, the evacuation of liquid fat took place, and amongst the morbid appearances the most remarkable was the condition of the pancreas, which was hardened and changed in structure, and its duct very extensively obstructed by calculous deposits. How far, then, we may hope to derive important diagnostic indications from these appearances of the dejections, still remains a matter of doubt; but there is sufficient to hold out an encouragement in the investigation. It is to be observed, that, in most of such cases, either jaundice or other evidence of biliary derangement has occurred; as, indeed, must almost necessarily happen, if there be any such connexion between the symptoms and the seat of the disease as that to which I have alluded. It may therefore hereafter be found that the peculiar evacuation depends simply on the state of the hepatic action. There is one other fact worthy of remark,—that in many of the cases in which the fatty dejections have appeared, some source of hæmorrhage from the intestines has existed, which was most remarkable in a case very lately published by Dr. Brown, in the periodical publication to which I just now referred; in which the discharge of fatty matter seemed almost to alternate with intestinal hæmorrhage.

The fæces are apt to assume particular appearances in their figure while passing through the rectum, which sometimes serve as indications of disease; more particularly where any unnatural constriction exists, as in malignant stricture of the part: but here we must bear in mind that spasmodic or habitual contraction of the rectum and sphincter will often produce this appearance, without any structural change; and there are two opposite causes capable of inducing this condition of the parts—one, the irritation produced by the perpetual employment of purgative medicines; and another, the state of disease into which the rectum falls when little fæcal matter passes, as in cases of scirrhus pylorus.

When examining the nature of the discharge from the alimentary canal, it is very essential that we should not suffer ourselves to be deceived by the appearances produced by various ingesta, some of which completely disguise the whole mass,

while others produce partial changes in the evacuated matters. Thus our remedies frequently change the colour of the fæces so effectually as to render all observations upon them nugatory. Steel, for instance, in all its forms, darkens the fæces, often rendering them black. Rhubarb gives them an unnaturally yellow colour, imitating the natural effects of bile. Hæmatoxylum gives an appearance of hæmorrhage, often very alarming to the patient; and castor-oil passes in a variety of forms—sometimes flaky, like fibrinous shreds, sometimes in globular masses, which have been mistaken for biliary concretions. Other remedies, by the effects they produce, are the cause of appearances which, if not borne in mind, might lead the practitioner to urge on his remedies, or to add a succession of counter-acting remedies, with unsparing and useless assiduity. Thus calomel will (in children more particularly) produce green dejections, which have been ascribed to collections of bile; and opium will artificially suppress the secretion of the bile, till the motions become almost as pasty as in jaundice. Articles taken in as food, will, independently of derangements produced in the processes of digestion, often prove sources of deception. Thus I have seen stools of a pitchy blackness, imitating melæna, stained by black currant jelly; and motions to all appearance loaded with green bile from eating spinach, while many vegetable matters, covered with epidermis, pass quite undigested, though perhaps slightly altered—the seeds of oranges, or the still smaller seeds of gooseberries, currants, and strawberries, the skins of beans, and the epidermis of dried fruits. I was once sent for in great haste by a gentleman who had just observed a curious appearance which he thought to be globules of blood floating in his dejections, but which were soon discovered to be currants he had eaten the day before in a mince-pie, now pulled up and distended by the warmth of the stomach and intestines, with their skins unbroken. A sailor-boy was put under my care in the hospital, who had returned about a week before from the Mediterranean, and on his voyage home had eaten figs freely. His case required purging, and very freely he was purged every day for a fortnight, at the end of which time a large number of the seeds of figs came away in a motion, though it was fully ascertained that he had eaten no figs for above three weeks.

Vegetable fibres also, as those of the stems of cabbage-leaves, have been brought to me as worms, or pieces of the intestine; but the most singular result of indigestible vegetable matter is found in the alvine

concretions, which are by no means of unfrequent occurrence in Scotland and some of our northern counties, and are the cause of a peculiar disease, in producing fatal obstruction of the bowels. Dr. Marcet and Dr. Wollaston have discovered, by analysis, that these concretions are composed of concentric layers of the fine hairy down from the internal skin of the oat, on which grain the poor people in those districts chiefly subsist; and alternating with these layers are others of the earthy phosphates.

Animal substances (as the membranous parts of veal), though more generally digested, will sometimes remain long in the stomach, or intestines, and pass after many days, but bones have remained much longer; and Dr. Locock mentioned a curious case of this kind which occurred to him,—the bones of larks having passed off many weeks after they had been swallowed, so that the fact had been forgotten, but they had in the meantime produced much painful irritation in the alimentary canal. Even the softest animal fibre will occasionally pass the intestines very little altered; of which I had an instance in a child who had long laboured under diarrhœa and almost total loss of digestion, for which cause it was found necessary to feed him on meat greatly comminuted, which therefore passed into the stomach with very little mastication. In the dejections many little red particles soon began to be perceived, which looked almost like altered blood, giving the apprehension of some ulcerative process; but these were soon found to be no other than the brown fibres of the meat, acted upon by the stomach and converted into red, as may be often seen when vomiting is induced some time after a meal of animal food. They had been hurried through the canal, and still retained their bright red colour.

[To be continued.]

MEDICINAL VIRTUES OF THE SMILAX ASPERA.

To the Editor of the Medical Gazette.

SIR,

WHEN new remedies are proposed, or substitutes offered for those already established in medical favour, it is remarkable with what caution they are received, not only into practice, but into notice. This circumstance may perhaps be highly creditable to the philosophical spirit of the cultivators of medical science. In the March number of the Medical and Physical Journal for 1831, I

introduced to the acquaintance of the profession a member of the family of smilax, well worthy of the attention of medical men. It is a cheap, and, as I now think, a very useful substitute for sarsaparilla. Since the date of my own notice, I have seen no published account of experiments tried with the smilax aspera, notwithstanding its more powerful agency for good or for evil in the human system than the remedy for which it has been offered as a substitute. Some physicians doubt whether the medicinal substances used as depuratives really exert any very beneficial influence on the constitution; while others are so wedded to sarsaparilla that they find it difficult to admit other remedies to any share of its transcendent reputation.

To a mind philosophically sceptic, there are no medicines that appear to deserve so long a probation as depuratives. The difficulty of putting their efficacy to a test, under circumstances which shall admit of no modifying influence—the time and patience required in investigating the peculiarities attendant upon their exhibition, and the varieties of constitution in which they are prescribed, leading to apparently discrepant results—all promote a bias towards a doubt, rather than a leaning to a conviction of their virtues. A length of time, many opportunities, and remarkable or striking effects are required to arrive at truth. Strongly impressed with this idea, I should have hesitated to occupy your columns with my inquiries, if I had not been urged by an interesting note from India to draw medical attention again to the virtues of smilax aspera. My intelligent correspondent dates from “Anjarakandy, 16th August, 1832.” In his communication this passage occurs:—“I lose no time in telling you that my friend R—, the surgeon at Tellicherry, and a very able practitioner, to whom I shewed your paper on the smilax aspera, has lately made a discovery as to the medicinal virtues of the plant, which, if confirmed on repeated trials, will be of the highest value and importance. He communicates to me as follows: ‘I have been putting smilax to another use. I have had in the hospital three severe cases of venereal. I put them under a course of it. One took it macerated in hot lime-water; another steeped in cold lime-water; and the third in boiling water. All rapidly improved. The

ulcers healed beautifully; and one of the patients who came into the hospital an emaciated, poor, thin, dying devil, soon, under this medicine, became plump and fat.’” I assure you, Mr. Editor, that it has been my lot to observe *plumpness* and *fatness* succeeding to a *cachectic* condition of body, under the use of preparations of smilax aspera, as well as of smilax sarsaparilla; and I may inquire what are the circumstances that determine this improvement of condition under the exhibition of these depurative medicines?

Those who are conversant with the use of sarsaparilla in this metropolis, where we have states of invalid health dependent upon a residence in an atmosphere vitiated, somehow or another, by the congregation of nearly 1,800,000 souls, will acknowledge that its therapeutic agency is upon the capillary and adipose systems. The mode in which a beneficial change is produced by it does not appear to be clearly established. It may be that it acts gradually through the emunctories of the skin and of the kidneys; perhaps of the liver. Dr. A. T. Thomson (London Dispensatory, page 560) tells us that it is said to be diuretic. Whatever may be its effect on the various organs influenced, that effect is produced in a very slow and almost in an insensible manner. There is no doubt in my mind of its efficacy in London, as a very valuable agent in numerous orders and species of cachexie and cæochymie. It appears necessary to state that the fact is such in this place, because very able practitioners in the provinces may be found who are sceptical as to the efficacious agency of sarsaparilla. Having witnessed the benefits it has conferred on many patients, I am convinced of its value. I have watched in vain, however, for its agency in strikingly or speedily altering the condition of any one or more of the secretions of the body; and, consequently, I was led some time ago to try the comparative effects of infusions and decoctions, containing innocent vegetable extractive with saccharine matter. Why are not these as efficacious as sarsaparilla? In rupia, in ecchyma, in pemphigus, in varieties of atrophia, especially in atrophia febrisequa, I have prescribed a decoction of triticum repens, with extract of liquorice; hay-tea and barley-water, with extract of liquorice, and sometimes with treacle; but though

the effects in many cases were not unattended with benefit, the amendment was most remarkable when sarsaparilla was substituted for any of them. It would exceed the limits of my present communication were the cases detailed in which these experiments were made. It is sufficient to state the general proposition, that extracts of the smilacæ have, in my experience, an efficacy in cachectic conditions for which we may look in vain to other vegetable extracts, the circumstances of adjunct remedies being the same. My object now is to inquire if *smilax sarsaparilla* be the valuable therapeutic agent I admit it to be—is there no other member of the same family equally valuable? I know not why the China root should have been so completely thrown out of English practice. In Singapore I found the Chinese doctors possessed of great faith in this drug. The chemical relations of this species are not very accurately known. Of the *sarsaparilla*, Dr. Paris (*Pharmacologia*, vol. i. p. 410) states the virtues to reside in fecula; and he says that it also contains a very large proportion of vegetable albumen. Dr. A. T. Thomson's account of *sarsaparilla* (*Lond. Dispens.* p. 560) may be reduced to a few points. A watery infusion reddens litmus, and affords precipitates to galls, lime-water, solution of nitrate of mercury, and superacetate of lead; but not to sulphate of iron, or any other metallic oxide. The alcoholic tincture is rendered turbid by water. Ether dissolves a yellow insipid resin. Galileo Pallotta has separated a white alkaloid from *sarsaparilla*; it is named *Parilline*.

Of the principles here manifested, none seems calculated to exert any very powerful influence on any one organ or set of organs. If it can be shewn that another species of *smilax* does contain principles that exert a striking influence on some of the secreting organs, that species is certainly worthy of attention, and in an especial manner, as it can be imported from various parts of the world at a rate of expense not exceeding one-half the price of *smilax sarsaparilla*. Mr. Garden's experiments upon the *smilax aspera* have established these points—that the distilled water from the root is slightly aromatic, and impregnated with its peach-blossom odour; reddening litmus, without any other character of hydrocyanic acid. The

decoction yielded an extract equivalent in weight to a fourth part of the root, possessing all its sensible properties; a pleasant and fragrant smell; a bitter and agreeable aromatic taste, with sweetness. From an alcoholic tincture was obtained a substance with a character between resin and wax; tasteless, inodorous, insoluble in water, softened by gentle heat, fusible at 260° Fahrenheit; at a higher degree, kindling and burning with a dull flame, emitting much smoke, but leaving no solid residue after combustion; soluble very sparingly in cold, readily in hot alcohol, which deposits it on cooling again; soluble in sulphuric ether, in the fixed oils, and in oil of turpentine: alcoholic and ethereal solutions having no effect on litmus or turmeric. A brown-coloured uncrystallizable fluid remained after the evaporation of the alcohol, possessing eminently the odour of the root, with its bitter aromatic flavour. This liquid, diluted with water, reddened litmus. The clinical observations I have made upon the exhibition of this material, have led me to conclude that it exerts a power upon the stomach, causing, in some cases, a gnawing, hungry sensation; upon the kidneys, producing sometimes an abundant diuresis; upon the head, occasioning a lightness, and in other cases a pain, requiring for relief an aperient remedy. In most cases, the use of *smilax aspera*, like that of *sarsaparilla*, has been attended with a beneficial change in the condition of the patient; plumpness, clearness, and strength, succeeding to emaciation, muddiness, and debility. To ensure brevity, I forbear to quote cases in support of my positions, trusting that in time the experience of others will bear out the accuracy of the present report. My own mode of administering this medicine has been that which I originally employed—a pint of the decoction, or of the infusion, in the day. The decoction has been made by boiling a pint and a half of water upon two ounces of the root, one drachm of the extract of liquorice, and half a drachm of the subcarbonate of soda, until the fluid is simmered to a pint. The infusion has been made by steeping two ounces of *smilax aspera* in a pint of boiling water, or in a pint of lime-water, for twelve hours; straining, and adding to the strained liquor two ounces of the syrup of *smilax aspera*. This latter

form of exhibition is convenient, and the flavour is very agreeable.

I remain, sir,
Your obedient servant,
JOHN ASHBURNER, M.D.

5, Wimpole-Street, May 28, 1833.

P.S.—Since the above was written, I have received from Mr. Belinaye the letter which is subjoined. His extensive observation and elegant formula give a particular value to the communication.

To Dr. Ashburner.

George-street, Hanover Square,
May 31, 1833.

DEAR SIR,

I HAVE delayed with regret complying with your request, business taking up so much of my time at the present period as to prevent my giving you that full account of my experience of the *smilax aspera* which I think you entitled to, since you are the person who has the credit of bringing it forward, and I happen to have been one of those who have prescribed it most largely.

Two years ago I happened to be called to attend upon a young nobleman, who, after a long course of dissipation, caught the venereal disease. Having taken large doses of mercury, he had to travel home in a great hurry, several hundred miles, without this remedy being cleared away, or the disease being perfectly cured. In his peculiar weak state I thought sarsaparilla the best remedy he could use, and I prescribed it. Independently of my apprehension that common sarsaparilla may be a remedy "*qui amuse pendant que la nature guerit,*" it is very subject to lay heavy upon the stomach, and to produce indigestion. In the above case the patient could bear it neither in its combination with the alkalies, nor with the mineral acids. Under these circumstances the "*smilax aspera*" happened to come under my notice, and I prescribed it to the complete restoration of the patient's health, who got remarkably fat and strong upon it, and has remained so for the last twenty months. From that time forwards I began to prescribe it frequently. In delicate persons I administered it in combination with one-eighth of a grain, more or less, of the oxy muriate of mercury, every night, and

with great success in the cure of syphilis, and of its bastard forms.

The complaint, however, in which I have administered this new remedy most abundantly and successfully, has been gonorrhœa. If it be remembered how difficult gonorrhœa is to treat; that if energetic remedies be administered at first, such as cubebæ, copaiva, and injections, the most distressing symptoms in the bladder, groin, &c. may show themselves; or if, on the other hand, gentle remedies be used, the disease frequently degenerates into interminable gleet;—if these circumstances be borne in mind, I think that the usefulness of any new remedy, capable of exerting a certain degree of positive effect, will be easily admitted. The following is the form in which I have prescribed the *smilax aspera* with efficacy in gonorrhœa, nearly exclusively from the beginning to the end of the malady:—

R Liquoris Potassæ mxxx. ad 5j.; Aq. Flor. Aurantii 5j.; Syrupi Smilacis Asperæ 5v. M. Sumat cochl. ij. ampla ter quaterve in die c Cyatho Decocti hordei magno.

I regret I have not time to run over the notes of cases in which I prescribed the above for gonorrhœa, and still more that I cannot find leisure to speak of the usefulness of the *same* formula in eruptive diseases, and in certain complaints peculiar to children.

Yours, in haste,

H. BELINAYE.

STRUCTURE OF THE PLACENTA.—

Examination of the HUNTERIAN PREPARATION at the College of Surgeons.

As the structure of the human placenta has lately excited much inquiry, the following statement is offered for insertion to the Editor of the Medical Gazette. It is an account of an examination of the Hunterian preparations relating to this subject, in the museum of the Royal College of Surgeons in London.

The preparation in the Hunterian museum which throws the most light upon the structure of the placenta, and upon the extension of the maternal circulation into it, is marked No. 3535.

The specimen is a triangular portion of a placenta, having a superficies of about four square inches, one of the sides of which is formed by the margin of the placenta, the other two being cut

surfaces, the depth of which at the angle at which they meet is an inch and a half. It consists of one entire lobe, and of portions of three other lobes of the placenta. Three kinds of wax injection -- one yellow, a second red, a third black -- have been thrown into it. The yellow wax, which appears to have been injected last, and more sparingly than the others, is seen to be in the umbilical arteries. The sources and place of the black and of the red injection, with the latter of which the portion of placenta under consideration is most coloured, will be pointed out afterwards.

The substance of the placenta is seen to be covered by two layers of decidua, one disposed on its uterine, the other over its fetal surface: these two layers of decidua meet of course at the circumference of the placenta. Upon one of the cut surfaces of the placenta, productions of the decidua are seen extending through the placenta from the fetal to the uterine layer of the decidua, which they unite.

Upon the uterine surface of the uterine layer of the decidua are seen orifices of different sizes, some containing red wax, others black wax. Some of these orifices are upon the surface of the lobes, others at the interlobular spaces. The orifices containing red wax open indiscriminately in either situation. The orifices containing black wax open principally at the interlobular spaces. It may be presumed that the orifices containing black wax were continuous with and injected from the uterine veins, and that those which contained red wax were continuous with and injected from the uterine arteries, upon the following grounds:—

The orifices containing black wax are larger, and lead into larger channels, than those which contain red wax. Some of those which contain red wax lead into channels which have the singular tortuous character described by Mr. Hunter, and by others, as characterizing the termination of the uterine arteries. And there is a preparation of part of an uterus, in the same series in the gallery, which there can be little doubt is that from which the specimen under consideration was separated, and in which the arteries are injected with red, the veins with black wax.

The orifices upon the uterine surface of the uterine layer of the decidua lead into flattened tubes of greater or less

length, which tubes appear to be regular channels, with smooth internal surfaces, formed in the substance of the productions of the decidua. Of these tubes, those which contain red wax are called, in the following description, *decidual arteries*; those which contain black wax, *decidual veins*.

One large decidual vein runs along the placental margin of one lobe. Another, of smaller size, passes nearly vertically in an interlobular fissure from the uterine to the fetal surface of the placenta. The former terminates opposite to an interlobular space at the edge of the placenta in two small decidual veins: one of these smaller veins opens into the extremity of the vertical interlobular vein, just described; the other extends along the fetal surface of the placenta. A third decidual vein, smaller than either of the preceding, dips into a different interlobular space, and after a course of a quarter of an inch, divides into two smaller veins.

Of the decidual arteries, those which open upon the lobules of the placenta make a sudden turn below the uterine layer of the decidua, and terminate there, forming the short curling arteries of Hunter. The interlobular decidual arteries descend nearly vertically towards the fetal surface of the placenta. One is seen to reach that surface, accompanying an interlobular decidual vein described above. Another, larger than the preceding, passes for the length of half an inch only into an interlobular space.

This preparation, therefore, distinctly establishes that there exist, formed in the decidua, and terminating on or extending into or through the substance of the placenta, regular channels, one class of which is continuous with and receives blood from the uterine arteries, while the other is continuous with and returns blood to the uterine veins.

The manner in which the decidual vessels terminate is best seen in those decidual arteries and veins which enter the substance of the placenta, but do not extend to its fetal surface. Each of the vessels of this class, that was examined, divides into two branches. These branches, after a short straight course, terminate abruptly. At their abrupt terminations, the tissue of which they are composed appears at more than one point to be porous. The smooth

lining of the decidual trunks does not appear entirely divested of the same character. This appearance in the decidual trunks is most distinctly seen in a large interlobular decidual vein. Immediately without and around the tissue in which the vascular channels are formed, is the injected and seemingly cellular decidual tissue of the placenta.

The preparation, No. 3535, would, indeed, leave it in doubt whether the red injection, with which it is coloured, is contained in cells, or in a series of minute decidual tubes, comparable to capillaries. But there are four other preparations in the Hunterian museum, seemingly taken from the same subject with that described, and in which the portions of uterus and placenta are not separated. Three of these, Nos. 3539, 3533, and 3538, and especially the first, certainly display a series of cells filled with black injection from the uterine veins. In one of these, numerous openings into cells from the side of a marginal decidual vein are distinctly to be seen.

There are other preparations which, taken singly, are less illustrative; but the whole beautiful series appears to us to establish in the clearest manner the correctness of the views which Hunter entertained of the relation of the maternal to the fetal circulation in the human placenta.

THE DERBY SELF-SUPPORTING DISPENSARY,

WITH REMARKS ON THE SYSTEM.

To the Editor of the Medical Gazette.

SIR,

THE animadversions on Mr. Smith's dispensary system, which have appeared in some recent numbers of the *Lancet*, must lose not a little of their severity by the acknowledgment of the editor that he is deficient of information on the plan which he condemns. With apparent ingenuousness he asserts, that if Self-supporting Dispensaries are really found beneficial to the public and the profession, they ought to be encouraged; and solicits information from

any individual who has witnessed their operations. In compliance with his request, I forwarded to him a copy of the rules of the one established in this town, together with the last annual report, and a letter, of which the following is nearly the substance. But as the sentiments contained in the letter were not in accordance with his preconceived views, I was not surprised that he should decline publishing it. However, as I believe that every unprejudiced and disinterested person, who is acquainted with its details, will hail the plan of Self-supporting Dispensaries, as an inestimable boon conferred on the profession as well as the public, and will readily yield to its philanthropic author the meed of gratitude and praise to which he is so justly entitled, I beg the favour of you to insert in your very valuable journal the following details of the Derby Dispensary, established nearly three years ago, and which, as far as its operations have extended, has hitherto fully answered the most sanguine expectations of its patrons. I am the more desirous to give this testimony to the admirable working of Mr. Smith's plan, as the abuses intended to be corrected by it are, in my opinion, of much greater magnitude, more derogatory to the dignity and respectability of the profession, and detrimental to society, than any which have been subjected to the discipline of the *Lancet*; and its adaptation to effect the purposes intended is no longer a speculative opinion, but rests on the firm basis of experience. The modification of the plan which has succeeded so well here, might also serve as a model for its adoption in other places.

The institution is intended to benefit three distinct classes of persons. 1. "Free class;" consisting of working mechanics and labourers. 2. "Charity class," or those who are too indigent, to subscribe as "free members," and who receive tickets of recommendation from honorary subscribers. 3. "Pauper class," or the parochial poor, the overseers of whose parishes contract with the managing committee of the Dispensary. Its designation is therefore, very properly, the "Self-supporting, Charitable, and Parochial Dispensary." The title of "self-supporting" is not the less appropriate because medicines are supplied to the "free class" by the subscriptions of honorary subscribers; as the first and

principal object of the institution—"to encourage a provident and independent spirit among the working classes"—is not thereby infringed, and the public are only enabling this meritorious and important portion of the community to help themselves, instead of depending, in times of necessity, solely on eleemosynary aid, which has a direct tendency to destroy that self-esteem which constitutes the independency of spirit so desirable to be preserved amongst them.

The institution is managed by a committee of twenty honorary subscribers. The medical officers form a committee of themselves, for the express purpose of taking care of their own interests, by objecting to the admission of persons who might be able to pay them in the usual way, and who consequently are ineligible to belong to the Dispensary. The two committees meet at the Dispensary, in separate apartments, every Wednesday evening, where applicants for admission as "free members" attend and are admitted, if their earnings are within the following scale:—"A single man, earning more than 12s. a week—a single woman, earning more than 9s. a week—also a man and his wife, whose joint earnings exceed 14s. a week—are severally inadmissible: 1s. 6d. a week may be added to the earnings of a married couple for each child dependent upon them. Domestic servants, lodging with their employers, whose earnings exceed 7*l.* per annum, are also inadmissible."

Applicants are first examined by the surgeons' committee, and their names, age, residence, employment, and weekly earnings, are noted down, and objections, if any, stated. The individual then takes this statement to the managing committee, who subject him to a similar examination; and, if found eligible, his name is enrolled, and he receives his "free member's" ticket on paying his subscription of one penny a week for adults, and a halfpenny a week for children under fourteen years of age, in advance up to the first Monday in the following month.

To render the subscriptions as easy as possible, they are paid on the first Monday in every month. A slight fine is imposed for arrears, which, if allowed to continue for three months, subjects the individual to expulsion; and he cannot be re-admitted without paying three months' arrears of subscriptions

and fines. No medicines are allowed as long as any arrears remain due.

Eight surgeons belong to the institution; at present there are only six, two having left the town. To prevent monopoly they continue in office only for three years, but are eligible for re-election. Elections take place without previous canvass. Each surgeon attends at the dispensary twice a week, at an appointed hour, to see patients; and those who are too ill to meet them there, are visited at their own houses by the surgeon of their choice. Any individual not a member, but eligible to be one, might have immediate attendance, if required, by paying his year's subscription, 4*s.* 4*d.*, in advance; at the same time an adult person must enter with him as a "free member." If a patient wishes to change his medical attendant, he is at liberty to do so only after the commencement of a quarter.

Charity Class.—Although this class is expected to consist of persons who are unable to subscribe as "free members," and do not receive parochial relief, yet, if their parishes are at a distance from the town, this rule is not enforced, and such individuals are eligible to receive charity tickets of recommendation. This indulgence is peculiarly beneficial in a manufacturing town like Derby, where vast numbers of strangers are induced to settle for the sake of employment, and in the event of sickness are wholly without means of obtaining medical assistance.

Pauper Class.—Owing to the prejudices which are always opposed to the introduction of innovations, however beneficial, the overseers of parishes have hitherto declined contracting with the Dispensary for attendance on the paupers. The advantages which it offers to the paupers are so great and indisputable, and the operations of the institution on the other classes so successful, that it is hoped before long the overseers will feel it an imperative duty to allow the Dispensary to supersede the notoriously objectional system of farming the paupers, which has hitherto been adopted, and has nothing to recommend it but long usage.

The fund appropriated to the surgeons consists of the subscriptions of the "free class," and also the contributions of the parishes whose overseers have contracted with the managing committee of the Dispensary, after deducting the supposed

cost of medicines consumed by the "pauper class." At the end of every quarter this fund is divided amongst the surgeons, according to the number of patients of each class indiscriminately for which they have prescribed.

All children brought to the Dispensary are vaccinated gratis.

Political economists violently exclaim against indiscriminate charity, and assert that eleemosynary institutions are so numerous in our country as to become a great evil; that the benevolence of the English character is greater than its prudence; that the poor have so much done for them, that they forget to do any thing for themselves; that the laudable spirit of independence which used to distinguish our peasantry is destroyed, and that they no longer consider pauperism a disgrace. It must be acknowledged that there is but too much truth in these assertions; but to correct such evils, and at the same time to direct the streams of benevolence into their legitimate channels, are the great and primary objects of self-supporting dispensaries.

The description of persons for whose advantage the "free class" is intended, forms a most important part of the community, which has hitherto been comparatively neglected, and no institution, with objects similar to that proposed by Mr. Smith, has been formed expressly for its benefit.

The most frequent cause of pauperism is disease. If a working man, on whose weekly earnings his family depends for subsistence, is deprived of health, he and his family have no other alternative than to become paupers. The health of such an individual is, therefore, of important consequence to the community; and the public only consult their own interest by affording him all possible facilities for securing this paramount blessing. We accordingly find, that where self-supporting dispensaries have been established, parish rates have visibly diminished. Without the powerful engine afforded by this dispensary system to the working man, when disease afflicts his family, he of course seeks for medical aid, and as long as he retains so much respect for himself as to shrink from becoming burthensome to the parish, he employs a medical attendant of his own choice; a bill is consequently incurred which he is unable to discharge. Sickness again

visits his house; the former bill not being paid, he sends for another surgeon, and so on, till he becomes indebted to as many medical men as will trust him—and in the end pays none. If he should be too honest to incur expenses which he knows himself unable to pay, the probable consequence is, that disease, which at first might have been easily removed, is allowed to make such ravages as to become incurable; thus practically contradicting the axiom, that "honesty is the best policy." Being in this way familiarized with dishonesty, he naturally becomes indifferent to character, and commences the slippery and downward path that leads to pauperism, which is no longer dreaded as a disgrace. Give him, on the other hand, the opportunity of securing to himself and family proper medical assistance during sickness, and let him feel that with a little provident forethought this might be effected by his own exertions, without outraging his feelings of independence by having recourse to charity, and he will retain the self-esteem which gives him the honest pride of independence—he will feel that he has a standing in society, and a character to support—and will shun pauperism as the legitimate offspring of idleness and profligacy.

This dispensary system not only affords to the working classes efficient medical aid when necessary, and in this respect places them upon an equality with their more opulent neighbours, but is intended to supersede the highly objectionable system of farming clubs and parishes, by one much more beneficial to the poor and creditable to the medical practitioner. It is well known that the farming of parishes is abundantly productive of disgraceful competitions, utterly derogatory to the profession, and that in most instances the paupers are miserably neglected. How can it be otherwise, when, as is generally the case, the lowest bidder is the successful candidate? and the remuneration is usually so paltry and inadequate as to prevent the surgeon from performing his duties efficiently,—for, by doing so, he subjects himself to positive loss; therefore, upon the principle of self-preservation he is obliged to be as sparing in his medicines and attendance as possible, and this class of patients is usually consigned to the care of his apprentices. The wretched pauper has no alternative but to put up

with the "parish doctor," or have none; and in many cases no doubt the latter is the less evil of the two. By the dispensary system, the sick pauper has the same privileges as other members of society; he can choose his own medical attendant, and can change him if he should feel dissatisfied with his attendance; he can have a consultation, if his case should require it, and as the surgeon is remunerated alike for each class indiscriminately, his interest is as much promoted by attending the pauper as the "free member."

Similar objections are applicable to the farming of clubs, which is productive of more detestable and disgraceful intriguing amongst medical men than even parishes, with this additional evil, that many individuals belonging to sick clubs are well able to pay for medical assistance in the usual way; and besides, the surgeon is usually taxed with attendance on the *families* of the members without receiving any remuneration, which he is fearful of urgently demanding, lest he should be deprived of the appointment, which he considers valuable, as affording an introduction to practice: thus the clubs take advantage of his peculiar situation, and he submits to a direct positive loss, in the hope of obtaining an indirect and uncertain benefit. If this abominable system were superseded by self-supporting dispensaries, the poor members of clubs might belong to the "free class," and those who are in better circumstances would be left, as they ought, to their own resources, and not be allowed to deprive the profession of the remuneration to which it is entitled.

The dispensary system is, I conceive, admirably adapted to promote the interests and respectability of the medical profession. It relieves the practitioner from the burthen of nearly gratuitous attendance on the lower orders of society; he is no longer called upon to outrage his feelings by making demands which are justly his due, on individuals whose earnings are barely sufficient to supply themselves and families with the necessities of life; he is no longer seen in the degrading situation of suing the poor mechanic at the Court of Requests, and obtaining an order for the payment of his bill by weekly instalments, of sixpences and shillings; his remuneration, although doubtless inadequate, is secure, and as it is for attendance and skill

alone, it is far more satisfactory, and much more creditable, than when arising from the precarious payment of bills for medicines. It effectually prevents the disgraceful intriguing, overreaching, undercharging and a host of abominations engendered by the hateful system of farming clubs and parishes; and the profession, relieved from these opprobria, which have hitherto acted like an incubus on its respectability, will retain the high standing in society, and command the respect and esteem of the public, to which it is so well entitled. It tends also to counteract the trickery and impositions of quacks and per centage physicians, who insinuate themselves into the dwellings of the poor, and prey upon their very vitals. The latter description of pests to society, I am happy to say, is rather an anomaly; but you must be aware, sir, there are such gentlemen, who stigmatize the profession by calling themselves "doctors," and obtain a livelihood by contracting with a druggist, to whom they send all their prescriptions, and receive in return a portion of the ready-money cost of the medicines: they charge small fees, and if these cannot be obtained, they *generously* prescribe *gratis*, and manage to make up the deficiency by prescribing *abundantly*. By the facilities for obtaining medical aid from the Dispensary, the deluded mechanic is rescued from the designing hypocrisy of such disreputable prescribers. Another, and not the least advantage, accruing from Mr. Smith's system, is the field for immediate action which it affords to the young practitioner, whereby his energies are not allowed to lie dormant, as is now too frequently the case, in waiting for practice. His exertions are immediately called into requisition, and his talents appreciated and quickly rewarded.

In conclusion, I may observe, that during the prevalence of cholera in this town, there is great reason to believe that the Dispensary had a powerful influence in restraining the extension of that dreadful disease. Although it continued occasionally to appear for several months, there were but twenty-seven cases reported, and fourteen deaths. Nearly fifteen hundred cases of various descriptions were treated by the medical officers of the Dispensary in the course of the year, many of which were diarrhoea, and would, no doubt, have termi-

nated in genuine spasmodic cholera, if prompt medical aid had not been afforded.

I beg to apologize for the length of this communication, and am, sir,

Your most obedient servant,

JOHN JONES,

Member of the Royal College of Surgeons, London; and one of the Surgeons to the Derby Self-supporting Dispensary.

Derby, May 14, 1833.

ON CERTAIN IMPERFECTIONS IN THE ACT OF 1815.

To the Editor of the Medical Gazette.

SIR,

I REGRET to perceive that hitherto my arguments have been thrown away upon you. Nevertheless, I do not despair; but trust, if you will give me once more your attention and a spare column, to convince you even yet that the Scotch have not buckled on their armour in an unjust cause.

In your last leading article you state that the measures of relief claimed by the Scotch Colleges will of necessity entail upon the existing race of practitioners in England and Wales all manner of evils—"burdens more intolerable than any which their predecessors knew of—a state of insecurity and primitive barbarism." Yet to effectuate such changes, every college and every constituted authority in Scotland which has any relation to medicine—professors and pupils—graduates *in esse* and *in posse*—have all been petitioning the legislature. There must surely be some latent injustice, some strong sense of rights withheld, or wrongs committed, which has thus associated together the men of Aberdeen, of Glasgow, and of Edinburgh. Let us consider for a moment what it is the Scotch ask, what it is they *do* possess, and what they *desire* to possess.

As the law now stands, a member of the College of Surgeons of Edinburgh may come to London, put upon his door ALEXANDER MACINTOSH, SURGEON, &c. practise in every department of the profession, become in every respect a general or family practitioner, and by charging at the rate of five shillings a visit, make a very comfortable livelihood without any fear of the Apothecaries'

Society or their solicitor, provided he takes the precaution of having his medicines made up at a chemist's instead of compounding them at his own home by help of his assistant or apprentice. In France, and I believe in almost all parts of the Continent, this mode of practice, this separation of the prescriber and the *pharmacien*, is universal. In some countries it is, I believe, actually enjoined by *law*. I will not stop to inquire whether such a thing is or is not *per se* desirable. No one can deny that it is a very good custom; and were it the custom of England, the Scotch would never have complained; but it is not. From time immemorial the English have been in the habit of receiving advice and medicines from the same person, and to that system they are still inclined to adhere. The Scotch, however, are unable to see why the compounding of a black dose in one shop rather than in another is to be the virtual cause of their exclusion from the great mass of English families. The law allows them to practise if they entrust the preparation of their medicines to a druggist over whom they have no control, but forbids them from practice, if they wish, by personal superintendence, to be satisfied of the purity of the drugs which they employ.

Turn it and twist it as you will, "to this complexion you must come at last." The "Apothecary" of the Act of 1815 differs from the "Scotch Surgeon" only in this, that the one may supply his patients with medicines from his own shop, and the other must send for them to the chemist's. This, in point of fact, makes, in England, all the difference between practice and no practice; but it will be impossible, I think, to persuade a Committee of either House of Parliament that such a distinction is defensible in theory, however well it may work in practice. It was the doctrine of the Conservatives, that schedule A worked well, and ought therefore to be retained. Parliament, however, decided otherwise. The rotten boroughs were disfranchised, and such, ere long, will be the fate of the obnoxious clauses of the Apothecaries' Act. Fear not, sir, that the public health will suffer from the change, or that the days will ever return when a smattering of medical education will suffice in this country. A flood of light has been let in upon the world since the peace of 1815, which

will not be extinguished even though the Scotch Colleges should be allowed to compete, on English soil, with the licentiates of the Worshipful Society of Apothecaries of London.

But, say some, the Scotch must be kept out, or they will overrun the country like a horde of Huns and Vandals. With as much justice might it be said that the youths of Yorkshire should be kept within the three Ridings, or they would overwhelm the men of Kent and Sussex. We need be under no such apprehension. The men of Scotland and the men of Yorkshire will take that place in the English counties to which their education and their knowledge of the world adapt them; and I have seen English pupils to little purpose if I have not learned that in the race of honour they may safely be trusted with even the choicest exports of the sister kingdom.

Before I conclude this, my last, letter on the effects and defects of the Apothecaries' Act, permit me to offer a few observations on the sins of *omission* of which either the Act itself, or its appointed guardians, have been guilty.

No one, sir, can have watched the practical working of this Act without feeling sensible of the immense improvement which it would derive from a system of *preparatory examination*. As it is, a young man comes to London on the completion of his five years' apprenticeship, occupies himself for two years in London, spends all his money, and when he goes before the Court of Examiners is found deficient in his *Latin*. This deficiency might just as well have been found out two years before, and being found out, would have either been corrected, or would have saved the young man the time, trouble, and expense of a medical education.

An examination at the close of the apprenticeship, and preparatory to his courses of *finishing* lectures, might advantageously extend to the translating of Celsus, the reading of physicians' prescriptions, the aspects and names of drugs, the elements of osteology, and Cullen's Nosology. This would insure a certain degree of diligence on the part of the pupil during his dull hours of apprenticeship, and it would be an additional inducement to the master to give occasional instructions and examinations. It is unreasonable to expect that, during the two years of his resi-

dence in London, a young man can beneficially occupy himself with his *hic, hæc, hoc*. All that ought to have been done long before; and if it has not been done, the youth should be debarred from prosecuting the higher branches of study.

The advantages of a preparatory examination are so obvious, that the Apothecaries' Society cannot have overlooked them. The Act of 1815, however, makes no mention of such a thing. We may therefore reasonably conclude, that it is to this omission in the Act, rather than to any doubt of the propriety of the measure, that we are indebted to the forbearance of the Court of Examiners. In any revisal which the Act may hereafter undergo (and I presume it is not intended to rival the laws of the Medes and Persians), the power of preparatory examination ought to be specifically recognized.

The only other point on which I shall venture to throw out a few reflections, is that of *counter-practice*, as it is called—in other words, the rights and privileges of chemists and druggists. There is a clause in the Act of 1815, by which chemists and druggists are authorized “to carry on their trade and business as fully and amply as they did carry it on prior to the passing of the Act.” This assuredly legalizes the practice of giving advice at the counter; for it must have been the custom in all ages, in cases of slight disorder, such as cramps, spasms, gripes, faintings, &c. It is certainly desirable to provide some cheap mode by which the poor may obtain the benefit of medical advice, without having recourse to the parish doctor; and I know of no better mode than counter-practice. It seems, however, quite necessary to provide, by some positive enactment, that chemists and druggists shall not attend patients at their own homes. This practice, like the Whig notions of kingly power, “has increased, is increasing, and ought to be diminished.”

With this, sir, I bring to a close my strictures on the Act of 1815. As I have nothing extenuated, so, I trust, shall I be found to have set down nought in malice. The Act has effected much good, and well merits the encomiums which you and the profession generally bestow upon it: but a good house admits of improvement, and in the lapse of years requires repair. Let us not

obstinately refuse to adopt those changes which reason sanctions, and which a whole nation concurs in demanding as an act of justice. If the claims of the Scotch be really just, they must ultimately be yielded; and the honour of England will better be consulted by prompt concession, than by waiting till the reiteration of complaint has enforced compliance.

I remain, sir,
Your very obedient servant,
MAXILLA INFERIOR.

London, June 3, 1833.

PETITION AGAINST THE SCOTCH APOTHECARIES' BILL.

—

To the Editor of the Medical Gazette.

SIR,
AT a meeting of the Surgeon-Apothecaries of this town, held on the 10th instant, the enclosed petition was agreed upon, to be presented as early as possible to the Honourable the House of Commons.

I beg to transmit a copy to you: the announcement of it in your valuable journal, which has so extensive a circulation, may rouse the medical practitioners of other towns to an expression of their feelings on the subject of the bill before the house.

I am, sir,
Your obedient servant,
F. F. LALLEMAND.

Macclesfield, June 12, 1833.

To the Honourable the House of Commons in Parliament assembled.

The humble Petition of the undersigned Surgeon-Apothecaries of Macclesfield, in the county of Chester,

SHEWETH,

That we have at very considerable cost of time and expense served apprenticeships of five years, according to the requirement of the law, and have subsequently attended due courses of medical lectures, and of hospital practice, and have obtained certificates of our fitness to practise our profession.

That we view with much apprehension the provisions of a Bill now before your Honourable House, for the amendment of an Act passed in the fifty-fifth

year of his majesty King George the Third, for the better regulating the practice of Apothecaries throughout England and Wales,—which provisions permit every person who has obtained a degree of Doctor of Medicine from one of the Universities of Edinburgh, Glasgow, or Aberdeen, or a diploma from the Royal College of Surgeons of Edinburgh, or from the Faculty of Physicians and Surgeons of Glasgow, to practise as an apothecary in England and Wales, provided he has served an apprenticeship (*of undefined duration*) to a regularly licensed medical practitioner keeping a laboratory for the dispensing of medicines, or having attended for at least months at the laboratory of a surgeon or apothecary, or of an established chemist and druggist, or of a public hospital or dispensary, and of having during that time been engaged in compounding and dispensing medicines.

That whilst such provisions will rapidly increase the number of competitors for professional practice, we conceive they will not tend to further the public welfare, as we are of opinion, that a five years' apprenticeship in the laboratory of a regular medical practitioner, with daily opportunities of compounding and dispensing medicines, and of witnessing their effects, combined with a subsequent extensive education in medical principles, is more likely to lead to a sound practical knowledge of, and experience in, our profession, than the uncertain and scanty requirements of the present Bill.

We, therefore, feeling that our interests may be materially injured by the enactment of the present measure, not only without advantage to, but with much probable detriment of, medical information, and of the public welfare, humbly pray that your Honourable House will be pleased not to pass the said Bill into a law.

And your petitioners will, as in duty bound, ever pray.

THOS. ROBERTS.	JOHN FLEET.
JAMES VERDON.	J. BIRCHINALL.
W. B. DICKENSON.	F. AINSWORTH.
JAMES COCKSON.	JOHN WAGSTAFF.
EDW. MILNER.	GEO. BOSTOCK.
F. F. LALLEMAND.	J. BRAITHWAITE.
EDW. FODEN.

MEDICAL GAZETTE.

Saturday, June 15, 1833.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

SOCIETIES FOR THE ADVANCE- MENT OF SCIENCE.

WE have looked through the volume which has just been published by the Provincial Medical Association*—the first fruits of that society, and the earnest, we trust, of its future activity and usefulness. We will not pretend, on the present occasion, to enter into the merits of particular papers (though we shall take an early opportunity of doing so); but the publication itself suggests to us a few remarks, which we see no reason for delaying to express.

It cannot but strike every one who is in the least degree attentive to the state of the scientific republic, that the present period is marked with peculiar features. That tendency, which has been observed to characterize the age we live in, to unite in large masses in order to accomplish great objects, has extended itself to men of science, forming no small portion of the community; and co-operation in purely intellectual, as well as in commercial and political pursuits, has become the order of the day. It is now generally felt and acknowledged, that power is in this mode greatly accumulated, and that an electric energy is current among those who come in contact in the course of their common labours. Such an event cannot but be hailed with pleasure by every enlightened member of the community; nor can the pleasure fail to be heightened in proportion as the newly-acquired power is regulated by fitting and wholesome laws.

One of the avowed objects of the Provincial Association is the following:—"Maintenance of the honour and re-

spectability of the profession generally, in the provinces, by promoting friendly intercourse and free communication of its members, and by establishing among them the harmony and good feeling which ought ever to characterize a liberal profession." If ever there was a time when steady co-operation for so excellent a purpose was needed, it is now; and if the new society had no other end in view than this, in its formation, its earliest efforts were well directed.

When the profession in England is threatened with *swamping* from the north, and a tide of adventurers openly aim at the trade rather than the cultivation of medicine as a liberal art, too much care cannot be taken by those who have really the advancement of medical science at heart. We perceive that a learned member of the Association has touched on this subject incidentally in one of the papers before us*.

A writer in a late number of the Edinburgh Review, noticing the state of the profession, very probably as it exists in his own latitude and within the limited sphere of his own observation, thus smartly observes—"Even medical men themselves are, in general, equally careless and incompetent judges as the public at large of all high accomplishments in their profession. Medicine they cultivate, not as a science, but a trade; are indifferent to all that transcends the sphere of vulgar practice, and affect to despise what they are unable to appreciate." Such is the taunt ventured upon by the reviewer even in the high places of medicine—at the much-boasted fountain-head of medical science—in the very teeth of those who affect to be the protectors of professional freedom and honour. Yet was it suffered to go unrebuked at its source; nay, some would whisper that the unseemly charge even emanated from some one

* The Transactions of the Provincial Medical and Surgical Association, vol. 1, 1833.

* Dr. Barlow on the Objects and Modes of Medical Investigation.

among the said potentates themselves. Dr. Barlow has taken the matter up, and, in a tone remarkable for its forbearance, observes—"Let us hope that the latter part of this pasquinade only shews the ignorance of the reviewer, and that it does not truly characterize the profession. Some ground for the imputation there may be; but if so, it results not from the general profession being liable to such a charge, but from its best energies being repressed and obscured by the manifold disadvantages under which it labours. Such is the public ignorance of professional merits, that individuals acquire a pre-eminence which, in a more enlightened state of the public intellect, they could never attain. These bring discredit on a profession, which, if its voice were to prevail, would never depute them its representatives. Professional merit is, no doubt, in many instances, patronized by the public; but the estimate is accidental, for they who decide are no adequate judges. But if the reproach thus cast by the reviewer attach at all to the profession so generally as is asserted, the fault would still lie, not with the profession, but with those who, by upholding ignorance and impudence, confound all distinctions, and take from merit its legitimate encouragement and support. The utter incapability of the public to form any just estimate of medical talent, acts as a positive discouragement to all laborious and enlightened research; and they who feel this depressing influence, if it were to extinguish their zeal (for that it does, I confidently deny), would have ample excuse, and would be entitled to every indulgence, were they, in weariness of spirit, to exclaim, 'if it happeneth to the fool even as to us, why should we labour to be more wise?' The sarcasm of the reviewer, as applied to the general profession, I believe to be unmerited; and if merited, it would still be unjust, inasmuch as the blame would be not

with them, but in the public ignorance of all physiological knowledge, and also in the political constitution of their own department, which makes no provision for distinguishing those whom the profession itself would delight to honour." Dr. Barlow concludes the topic by giving in evidence that the profession, at least in this country, is not in that degraded state represented by the northern writer—the fact of the almost simultaneous and widely-pervading zeal which has, on the call of a single voice, so promptly formed the association of provincial practitioners.

From the proceedings of a society so effectively organized, and animated with so noble a purpose, we cannot but augur the most cheering results. But we must not forget that there are other objects, scarcely less commendable, which may be said to form the proper vocation of this learned body. Increase of knowledge, and the advancement of medical science, are inscribed upon their banner; and by the zeal which they evince in this pursuit, it is, we presume, that they are ultimately to stand or fall. Medical societies there have been, and there are, in abundance throughout the country; but none, perhaps, was ever instituted with so avowedly fixed a determination to *advance* medical knowledge. Other societies would seem, in comparison, to have been formed merely to *mark* the progress of science; but of this, and the other noble association lately established, the design expressly is, not so much to mark, as to *make*, progress by the united activity and co-operation of their several members.

With this view, the provincial society has sketched out skilfully the several departments in which members, and groups of members, may distinguish themselves with most advantage to the cause of science. The chief details regarding this arrangement have been given to the public in the original cir-

cular, and in the luminous address of Dr. Hastings, pronounced before the Association at Worcester last year. We will, therefore, take leave to pass at once to the notice of Dr. Conolly's plan, which, of all the expedients yet devised for tasking the usefulness of the society, seems to us to be the most promising. It is proposed by this gentleman to turn the services of country practitioners, even of those the most isolated, to account; and this for the purpose of procuring a body of local statistics, such as no other persons than the practitioners just mentioned are better furnished with the means of collecting. The medical man, situated in a rural locality, "not only becomes thoroughly familiar with natural scenery, the character of the surface, and the climate of his own district, but he knows the occupations, the habits, the characters, even in their minutest traits, of all his patients, and almost of all his neighbours; their prosperity or adversity are never hidden from him, and their most secret griefs and cares are confided often to his ear alone. By the time that he has practised ten years in any one place he has learned the history and constitution of every family in his neighbourhood by observations made on two, or, more generally, on three generations*." Nor is his observation confined to the personal circumstances to be gathered from his professional intercourse and experience. His opportunities of noting the local peculiarities, both as regards the soil, climate, water, &c. of the district, and the diet, moral character, prevailing diseases, &c. of his fellow-residents, are unrivalled. Nobody has better means of observing the consequences of peculiar habits in his patients—the effects of early and late marriages—of temperance and excess—peevishness and contentment—late and early hours—family afflictions—a good or neglected education.

* A proposal to establish natural history societies, by J. Conolly, M.D.

With such great and manifold opportunities, of which those enumerated constitute but a small part, it is justly considered by the author of the plan that the country practitioner has ample means of being eminently useful, and that the society should accordingly be divided into sections, which would call the talents of every individual member into requisition. Thus there would be sections of statistics, topography, natural history, &c. the members of which should meet quarterly, and arrange their observations, so as to afford an easy comparison with those of preceding and corresponding periods. We would merely observe that we have some doubts of the practicability of these quarterly meetings; nor do we see precisely their necessity. With well-arranged blank forms, and occasional transmission by post to an official personage, who would act as Secretary to the section, we think that every thing might be managed just as conveniently, without requiring a personal meeting oftener than once a year. The suggestion about publishing local *Annales*, containing, amid a variety of useful and interesting information, meteorological tables, accounts of epidemics, reports of hospitals, bills of mortality, population, &c. however excellent, must, we fear, give way before one simple extinguisher—the tax upon almanacks.

For the present we must close our remarks, promising soon again to return to the subject.

APOTHECARIES' AMENDMENT BILL.

THE second reading of this Bill, which was set down for Friday the 7th, and again for Thursday the 13th, has been a second time postponed. It now stands for Tuesday the 18th; but we venture to predict, *never will be passed in its present form*. The gentlemen at the Home Office, we have reason to believe, are beginning to take a different and more correct view of the matter, and one which is likely to lead to a satisfactory arrangement. The Colleges of

Surgeons and Society of Apothecaries ought not, as now, to be placed in a kind of rivalry, but rather to co-operate in securing to the public the best educated practitioners, and to the profession the greatest share of respectability. There must be some test of the *medical* knowledge of general practitioners; and this would be foreign to the business of a College of Surgeons, whose testimonial, on the other hand, as to anatomy and surgery, ought to be without appeal.

We hope next week to be able to announce that this knotty piece of legislation has been brought to a conclusion more suited to the exigencies of the case than was promised by its commencement.

FACTORY COMMISSION—REMUNERATION OF PRACTITIONERS.

To the Editor of the Medical Gazette.

SIR,

I ENCLOSE you the following correspondence, which, if you think fit, you will oblige me by publishing in this week's *Gazette*. The perusal will shew you I did not think it just to call for the labour and intelligence of the medical practitioners in the country, to give information to *paid* commissioners, without an adequate remuneration. I hope you will be the means of shewing to distant practitioners what I have tried to do in behalf of our profession.

—I have the honour to remain,

Most obediently,

JOHN CALTHROP WILLIAMS.

Nottingham, June 11, 1833.

No. 1.—(Copy.)

To the Right Honourable the Secretary of State for the Home Department.

Nottingham, June 4, 1833.

MY LORD,—I yesterday received (I believe in common with every member of my profession in Nottingham) *several post folio* sheets of paper, in which were printed one hundred and four questions, with the following order printed on the outside—"You are desired to return this by the 10th of June at the latest." I have carefully perused those questions, and it is my opinion they cannot be answered with sound judgment, founded on facts, notes, and observations, without the devoting of at least some hours daily for some time.

Knowing that the Commissioners are to be remunerated by payment from the public purse, I ask of you, my Lord, whether the medical practitioners resident in populous towns and districts, and from whose talent and industry the very marrow of

the information is to be obtained, are to be remunerated also, for the time and labour they are asked (by the paid Medical Commissioners) to devote for the supply of information to those *paid* Commissioners? I ask this question on public grounds, and shall take the earliest opportunity of acquainting my professional brethren with the contents of this letter, and your Lordship's answer.

I have the honour to remain,

My Lord,

Your obedient servant,

JOHN CALTHROP WILLIAMS, M.D.

No. 2.

To Dr. J. C. Williams.

Whitehall, June 5, 1833.

SIR,—I am directed, by Viscount Melbourne, to acknowledge the receipt of your letter of the 4th instant, and to inform you that his Lordship will transmit it to the Factory Commissioners, and desire them to communicate with you upon the subject to which it relates.

I am, sir,

Your obedient servant,

J. M. PHILLIPS.

To Dr. J. C. Williams, Nottingham.

Factory Commission, June 7, 1833.

SIR,—With regard to your communication of the 4th inst. to Lord Melbourne, which has been transmitted from the Home Office to the Central Board of this Commission, I am directed to say that it cannot have been intended by Dr. London to desire any degree of aid from professional men inconsistent with their private practice or avocations, and that some misapprehension must have arisen on the subject. I am farther directed to say, that although in certain cases the Board have felt themselves authorized to offer remuneration for valuable services, it is impossible to enter into any general engagement with regard to future services which they have no means of estimating.

I have the honour to be, sir,

Your very obedient servant,

JOHN WILSON, Secretary.

To John Wilson, Esq. Secretary to the Central Board Factory Commission.

Nottingham, June 9th, 1833.

SIR,—I have to acknowledge the honour of a letter from you as Secretary to the Central Board of the Factory Commission. I did not in my letter directly or indirectly impute to Dr. London, or to the Medical Factory Commissioners, the "desire for any degree of aid from professional men inconsistent with their private practice or avocations," and I regret such a "misap-

prehension" on the part of the Central Board on that point. Tasked, in allusion to the one hundred and four questions sent to me, and to others of my profession, whether the medical practitioners were to be remunerated also for the exercise of their talent and industry in supplying information to Commissioners paid by the public? As my inquiry was on public grounds, and referable only to those one hundred and four questions, as I consider your letter an unsatisfactory answer to a specific question, and, as it appears by that letter, that the Central Board "have no means of estimating the value of future services" in collecting and arranging information necessary to answer those one hundred and four questions, so, for these reasons, I decline occupying my time with these one hundred and four questions, and return the post folio sheets sent to me. I shall now communicate this correspondence to my medical brethren, and I have the honour to remain, sir,

Your most obedient servant,
JOHN CALTHROP WILLIAMS.

MIDDLESEX HOSPITAL.

Thirty one Fractures in one and the same individual.

THERE was lately in Bird's Ward an extraordinary instance of the facility with which the bones of the body are occasionally broken and reunited, in the person of Eliza M., fourteen years of age, who was admitted April 29th, under the care of Mr. Arnott, for fracture of the right thigh, in consequence of a fall. This, according to the account of the mother, is the thirty-first fracture which her daughter has experienced; and the girl, who is quick and intelligent, states the particulars thus:—The right thigh has been broken seven times, the left six; the right leg nine times, the left once; the right arm four times, the left three; and the left forearm once.

Eliza M. was about three years of age when the first fracture, that of the left leg, occurred from a fall, and she has never fallen since without fracturing a limb. But even this is not necessary, for she has broken a bone by merely catching hold of a chair, and sometimes in simply turning round suddenly. She has a sister six years of age in whom there exists the same susceptibility, and who, since the age of eight months, has had nine fractures. In neither of the parents or their families has there been any similar disposition, nor in three others of their children, two boys and another girl.

There is nothing peculiar in E. M.'s appearance. She has delicate features, a fine skin, dark hair and eyelashes, and bluish

grey irides. The bones of the trunk and upper extremities present no alteration from the natural form, but those of the right leg are strongly arched forward, and so is that of the left thigh; in a trifling degree this is the case with the left leg and right thigh. Besides the curve forwards, the bones of the right leg seem to be flattened laterally, as in *rickets*, but no curvature existed before the bones began to break. A variety of medicines were formerly tried in this case, with a view to remedy the great brittleness (as it has been called) of the bone; but the mother states that she never found them to be of the least benefit. She speaks, however, in strong terms of the advantages derived from a residence at the sea-side, and nourishing diet.

No difficulty has ever been experienced in getting the bone to unite—so little that the mother has treated many of the fractures, (those not attended with displacement,) herself, and has of late sought surgical assistance only when the larger bones were broken. Thus the girl was in this hospital about two years ago for a broken thigh, and this interval is the longest she has ever experienced without a fracture.

The thigh bones, and those of the arm, have never broken without displacement; those of the leg have. It would seem as if, in the case of the latter, the fracture had not always been complete. Her health suffering, this girl left the hospital on the 28th of May, but Mr. A. mentioned the other day that he had since called at the residence of her parents, and found her doing well. The limb had been treated on the double-inclined plane with splints which were continued at home. E. M. does not walk without a crutch, and it was in consequence of this slipping that she met with her last accident; but Mr. A. found her sister, who has had the nine fractures, running about without any assistance of the kind, and in a state of apparently perfect health.

Stricture of the Oesophagus—Scirrhus of the part.

James S. art. 49, was admitted April 2nd, 1833. Is unable to swallow solid food of any kind. Can swallow fluids, but with difficulty; and when bread has been made into thin panada with milk or water, he contrives to get some of it down. Deglutition is slowly performed, a small quantity is taken at a time, and having been thrown into the bag of the pharynx, it appears to stop there, when, after continued but gentle efforts at swallowing, the fluid gradually passes, and he is enabled to repeat the attempt. This process is unattended by pain. When asked where he feels the obstruction, he points to a situation corresponding to the commencement

of the œsophagus; and here, on introducing a bougie, it is stopped, just at the bottom of the pharynx. No swelling or induration can be discovered here, and pressure does not give pain. He has become greatly emaciated, and his countenance is wan and sallow.

Has been subject to difficulty of swallowing for the last six months. This was first observed in consequence of a piece of meat sticking in his throat: assistance being obtained, either a bougie or probang was passed, and he brought up the morsel again. A bougie was now passed several times; but going soon afterwards into the country, this was neglected, and he has since got gradually worse. For the last three months he has not swallowed meat.

On the second day after J. S. entered the hospital, œdema of the feet was observed, and, on examination, water was detected in the abdomen. Various attempts were made to pass a bougie through the stricture, but even the smallest sized urethra bougie could not be made to pass. With as little avail was a catheter properly bent tried, and an instrument on the principle of that recommended by Mr. Fletcher, in his *Medico-Chirurgical Notes*. Leeches applied to the throat the patient described as being of advantage, but this was not observable by others. The ascites increased, being temporarily relieved by elatium; and ere it reached to oppressive distention, the patient died, worn out, on the 1st of May.

Ten days before his death, a small indurated nodule was felt on the left side of the neck, immediately below the seat of stricture.

Autopsy.—Excessive emaciation. Abdomen greatly distended. Thyroideal veins large, and full of blood. No adhesion of the pharynx and œsophagus to the neighbouring parts; they were readily removed with the larynx and trachea. Viewed now from behind, a puckering of the soft parts over the commencement of the œsophagus was observed, and the parietes of the canal, here contracted in size for the extent nearly of an inch, felt as solid and hard as cartilage. This alteration of structure encroached a little on the pharynx. On slitting up the diseased portion of canal through which even now the small plaster bougie could not be made to pass from its contraction and irregularity, the divided surface presented a white opaque smooth appearance, uniform, like that of cartilage, and without any intermixture of striæ. At the middle part, it was impossible to say where the disease had originated, all the coats having become involved, but both at the upper and under end the diseased change was seen to be limited to the internal coat; for here the external cellular,

the muscular, and the subjacent cellular or nervous coat, as it has been called, could be raised unchanged from the enormously thickened and indurated mucous coat. Viewed from the interior of the canal, the limits of the morbid alteration in structure were distinctly marked by a corresponding elevation of the inner surface of the mucous membrane, the edges of which in some places overlapped the sound portion. The elevated and diseased surface was not ulcerated, yet it seemed abraded. In its distinct limits and some other characters, the induration resembled the scirrhus tubercle of the skin. The nodule felt on the left side of the neck, a short time before his death, was an indurated gland.

The viscera of the chest were healthy.

A large quantity of serum was contained in the abdomen. The liver, apparently somewhat less than natural, had a tuberculated surface, and felt hard. On the convex part of the large lobe, the extremity of a small cyst, slightly raised above the level, presented itself, and being opened, was found to contain a large number of calculi, probably 100, with a little bile. The calculi were small, white, and pearly: they were composed of almost pure cholestrine. This *additional gall bladder* was formed of a dilated biliary duct. The real gall bladder contained bile, and no calculi. Sections of the liver presented, in a slight degree, the nutmeg appearance.

MEETING OF THE ASSOCIATED GENERAL PRACTITIONERS.

In addition to the petition from Macclesfield, given in a former page, we are glad to find that a meeting of the "Associated General Practitioners" took place on the 12th, at the Crown and Anchor Tavern, when the following resolutions were passed:—

1. That the Act of Parliament passed in the year 1815, commonly called the Apothecaries' Act, had its origin in this Association; that this Association has ever since taken a lively interest in the operation of this Act, both as a public benefit and as raising the character of the general practitioner.

2. That while this Committee concurs entirely in the following resolution, passed at a General Meeting of the Association, held at this house, June 21, 1820, this Committee is of opinion, that the course of medical education required, and the strict examination instituted by the Court

of Examiners of the Society of Apothecaries, have greatly raised the whole medical profession in the estimation of the public, and have been the means of keeping out of general practice very many incompetent persons:—

“ Crown and Anchor Tavern, Strand,
June 21, 1820.

“ At a General Meeting held this day,

“ Resolved, 14. That the General Meeting feel themselves called upon to express very strongly the grateful sense they entertain of the benefits which have resulted to the public and the medical profession from the zealous and active exertions that have been made by the Society of Apothecaries in carrying the Apothecaries’ Act into efficient operation.”

3. That the Bill now before the House of Commons virtually repeals the most beneficial clauses of the Act of 1815, removes all control over unqualified practitioners, and is a great injury to the whole people of England and Wales, by depriving them of every means whereby they may judge of the qualifications of medical practitioners.

4. That the said Bill, if passed into an Act, will benefit those persons chiefly whose general and medical education has been so deficient as to give them just reason to apprehend their rejection by the Court of Examiners of the Society of Apothecaries, notwithstanding they may have previously obtained degrees or diplomas from the universities or colleges of Scotland.

5. That a petition, founded on the above resolutions, and praying for inquiry, be laid before the Commons House of Parliament, and that George Byng, Esq., the member for the county, be requested to present the same.

Another meeting is called for June 21st, at six in the evening.

Wind S.E. and S.W.; the latter prevailing.

Except the 11th and 12th, generally clear.

HURRICANE.—On Tuesday last we were visited by a more violent storm of wind than has perhaps ever occurred, certainly not remembered, in the month of June. At sun-rise the atmosphere was calm and cloudless, and so continued till near seven, when the clouds rose, and the wind blew in violent gusts, carrying away leaves and fruits of all trees exposed to its force. The storm, however, was not at its height till noon, from which time till near five it blew with such terrific violence, that many lofty elms and oaks were torn up by the root and thrown upon the ground. In several gardens the trees have lost more than half their fruit. The appearance of the leaves is that of having been parched by heat, arising, however, merely from the violent concussion. Hay-making, which had been in most cases deferred till the 10th, in hopes of rain, was a complete scene of confusion; any attempt to keep it together in the open field was fruitless, and in some cases the meadow parted with its grass to cover a field of potatoes; while in other cases, where adjoining fields have been the property of more than one, it has led to strange controversies as to how much the neighbour's field may have been benefitted by the gust of wind.

CHARLES HENRY ADAMS.

NOTICE.

Unluckily, the corrections in the opposite column were not in time for the *Lancet*. Our worthy contemporary has this week given Dr. Ley's paper, even with the misprints which we regret to observe, by some accident, were contained in our edition published a fortnight ago.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE HEART.

—
AUSCULTATORY SIGNS.

Cause of the various preternatural sounds not known.—Why it is that you have sometimes a bellows sound, and sometimes a sound resembling the action of a saw or file, is not well known. Some have supposed that when there is ossification you have a shrill sound, but that is not proved. I should imagine that it depends on two or three things together. If the opening be very small, and the action of the heart is driving on a large quantity of blood, I should think it would be shrill; but if the opening be small, and the action of the heart not very strong, then the feeble influence of the blood will not cause, I should think, the shrill sound. If the parts were soft, then you might have a shrill sound.

Auricle supposed to contract before the Ventricle.—It has been supposed that the auricle contracts before the ventricle, for this reason—that in the case of an obstruction, you see the jugular veins swell at the time of the stroke of the heart;—before, indeed, the pulse is felt, the jugular veins will sometimes swell in a case of disease of the heart, and pulsate strongly. It is supposed that when the auricle contracts, then an obstruction must take place in the veins, and the blood accumulate there. I do not, however, myself think that at the time the auricles contract there is any obstruction in the veins at all, for when they lose their blood the ventricles must be open for the blood to rush into them, and, conse-

quently, there is a free passage for the blood. When the ventricle is contracting, there must be a great obstruction to the blood, certainly, but the moment the ventricles dilate, that moment the auricles act, and the action of the auricle cannot cause an obstruction, because there is a free course for the blood to rush into the ventricle. It is hardly possible to make you understand the subject in a lecture, but you will see the arguments at page 16 of my book.

Preternatural sounds after the pulse—on what dependent.—Now you cannot say with certainty, when you hear these peculiar sounds a moment after the pulse, and after the action of the heart, that they arise from a difficulty to the transmission of the blood from the auricle, and for this reason: if the valves at the mouth of the pulmonary artery and the aorta (and the latter is very common) do not do their duty, but let back a portion of the blood, I believe the rushing back of a small quantity of it will occasion the bellows sound. You are aware, that the moment the ventricle has acted and dilates again, the blood attempts to rush back into the vacuum, but is prevented by the three aortic valves, which are filled out in a moment. But if it so happen that one is torn, or becomes corrugated and small, then a certain portion of the blood will regurgitate; and as it is not the whole of the blood in the aorta that can go back, but a minute portion that passes through the small opening which is left (the valves doing their duty to some extent), that is sufficient to cause the bellows sound. If the whole of it regurgitated, doubtless there would be no bellows sound; but if only one valve be torn, if only one valve be corrugated, or if the whole of the valves be partially corrugated, then the small portion which returns causes the bellows sound. Now you will see that this must take place synchronously with the emptying of the auricles. The same cause which makes the blood rush from the auricles, viz. the dilatation

of the ventricle, also attempts to make the blood rush back from the aorta and pulmonary artery into the ventricle. The blood attempts to go from the auricles, and does so with success, and at the same instant it attempts to do so from the aorta and pulmonary artery, but cannot; and it is at this moment that we have the morbid sound. Suppose it is one of the auriculo-ventricular openings that does not do its duty—suppose the tricuspid valve on the right side, or the mitral valve on the left, is bound down on one side, or suppose it is diseased, so that there is a constant aperture there, and a certain portion of blood must therefore rush back from the ventricles into the auricles—then you have a bellows sound from this cause at the time the ventricles contract. I have heard a bellows sound frequently at the moment of the pulse, arising not from an obstruction to the course of the blood out of the ventricles, but from a valve between the auricles and ventricles not doing its duty, so that a small portion refluxed; and before I was aware of this circumstance, in one or two cases I gave a false diagnosis, and said that there was an obstruction to the course of the blood from the ventricle, whereas it turned out that there was a valve between the auricle and ventricle not performing its functions properly. Hence, when there is a bellows sound at the moment of the heart's action, it may arise from disease of the aortic valves, or disease of the mitral valve; and when the bellows sound takes place after the pulse, it may be the result of an obstruction to the course of the blood from the auricle, or from a certain portion rushing back into the ventricle. You may say in every case that it is caused by one of these two circumstances.

The first case in which I found I had made a false diagnosis was one of which I have given an engraving; the preparation is at St. Thomas's Hospital. There was a loud bellows sound at the moment of the pulse, and I therefore concluded that there was an obstruction at the mouth of the aorta, or the pulmonary artery; but I found that the tricuspid valve was bound down, so that there was a constant opening, and when the ventricle contracted the blood refluxed freely into the auricle.

Various causes of diminished apertures.—Now you may have these diminished openings from various causes. Sometimes the valves are diseased in the way I have shewn you. The valve may be indurated, become cartilaginous, become bony, and the opening may be organically diminished. The aperture is sometimes decreased by excrescences. Twice I have seen the valves perfectly sound, and the pulmonary artery contracted immediately beyond the

valves, so that a very minute aperture only existed for the blood to escape through. In one of these cases the disease arose, as it does in so many instances in young persons, from violent pericarditis. The pericarditis had gone on to produce cartilage under the pericardium, and the cartilage had dipped down so much into the substance of the heart, that it pressed upon the origin of the pulmonary artery, and there produced a great obstruction. In that case there was a bellows sound heard at the moment of the pulse. I heard it on the right side of the heart's region, in the situation of the right ventricle, and it was written down in the hospital books, "difficulty to the transmission of the blood from the right ventricle to the pulmonary artery." What the cause was I did not know, but a mass of cartilage existed in the substance of the heart, extending from the inner surface of the pericardium down into the substance of the heart, where it produced a great diminution of the calibre of the pulmonary artery. You will find a representation of the case in one of my plates. I have never met but with two cases of obstruction of the pulmonary artery. Disease of the valves of the pulmonary artery is exceedingly rare; in fact, you are aware that all diseases are far less common on the right side of the heart than on the left. In the second case the diagnosis was equally correct. There was a loud bellows sound on the right side of the heart at the moment of the pulse; and after death just such a disease was found as I have now described to you—that is to say, the pulmonary artery was exceedingly diminished, so that the blood could not escape from the ventricle. There is an engraving of a case in my work which I did not see, and therefore do not know what the particular symptoms were, but there was a loud bellows sound. The case occurred at St. Bartholomew's, and the heart was shewn me when lecturing at the College of Physicians. The patient was a young woman, and died from this affection. I should think it was a case of malformation, because I did not perceive any sign of disease of the heart. She was dropsical all her life, and at last there were signs of great obstruction. The older she grew, the more the heart grew, but the opening never enlarged. There were more and more ill effects the longer she lived. These are very rare cases, indeed. If any thing by chance press upon the aorta, or upon the pulmonary artery, you have this bellows sound. Although there may be no disease of the vessel itself, no disease of the valves, no disease of the opening, yet extreme pressure will have the same effect. I recollect at this moment, that I saw a case where

there was a piece of bone between the aorta and the pulmonary artery, and it pressed on both; there was a bellows sound at the time of the pulse, on both sides of the chest.

You may, however, have a preternatural sound (I say we had better use the word preternatural as a generic term, to include all these sounds) while the opening remains quite natural—quite as it should be. The cavity, however, behind the opening is very much dilated, and in that way the opening is *relatively* small, although not absolutely. Nature, of course, has just given an exact proportion between the size of the openings and the cavities; and the natural dimensions are those which allow the blood to pass through in the most easy manner and with the least noise. Thus the natural proportions, you perceive, may be destroyed in two ways: the cavities may remain the same, and the openings become too small; or the openings may remain the same, and the cavities become too large; in which case the openings are no longer large enough for the cavities, and in either case you have the bellows sound. You must not be surprised, therefore, after a bellows sound, to find the openings in a natural state, because the cavity may be too large; nay, when this is the case, the least alteration in the position of the heart will sometimes cause a bellows sound, and by position the free course of the blood from the left ventricle may be destroyed. I once had a very curious case of this kind. A woman laboured under ascites, and I found a bellows sound in the heart. I was anxious to know the cause of the ascites, and wished to ascertain whether there was organic disease. I examined the heart, and found a bellows sound at the moment of the pulse. She was tapped, and no sooner was the operation performed than the bellows sound went away. The water accumulated again, and with it the bellows sound returned. Now in this case the opening was found healthy after death, but the left ventricle was dilated. It appeared to me in that case, that the ascent of the diaphragm by the water tilted the heart a little, prevented it from being quite in its natural situation, and caused the apex to rise in that way that the passage of the blood into the aorta would be a little impeded. If the position of the heart be altered, if the apex be lifted up, no doubt the blood will experience a difficulty in going into the aorta. In this case it was quite proved that it arose from some such circumstance, because, when the heart was pushed up through the diaphragm by the water, there was a bellows sound; and when the diaphragm was let down, the heart going with it, the bellows sound ceased. In any

case where you hear a bellows sound at the moment of the pulse, you *may* find pressure from the abdominal viscera. When a person is upright, and the bellows sound takes place at the moment of the stroke of the heart, if you make him lie flat, from the abdominal viscera pressing up and the apex becoming a little tilted, you find the bellows sound increased. I have frequently not heard the bellows sound at all when a person labouring under disease of the heart has been standing up; but on making him lie down, I have heard it distinctly. In almost all cases, when there is a bellows sound at the stroke of the heart, arising from an obstruction to the blood in passing from the left ventricle, if you make the patient lie down you hear it with greater force; and I should advise you, therefore, in these cases, to listen to the sound in both ways. I presume the circumstance arises from the same cause when a bellows sound is heard in the case of the aorta. The abdominal viscera, when a person lies down, press against the diaphragm, and alter the position of the heart, so that the blood cannot so easily escape from the aorta. You know that when there is difficulty of breathing patients wish to sit up, and then the heart falls more into a vertical position. In hypertrophy of the heart you frequently hear a bellows sound where there is no great dilatation. If it so happen that the substance of the heart is much thickened—that the columnæ carneæ are much thickened near the mouth of the aorta, towards the semilunar valves—the increase of the flesh of the heart will cause a little obstruction; so that you have a bellows sound. Frequently, therefore, in opening bodies where there has been a bellows sound, you find some other cause than disease of the opening; you may find something pressing on the outside of the aorta—you may find the substance of the heart increased—you may find the heart out of its due position—you may find the cavity behind the opening so much dilated, that the latter, although of its natural dimensions, is not big enough for the enlarged cavity which forces its blood through it.

The Bellows Sound sometimes a temporary affection.—It would appear that sometimes this is only a temporary disease, dependent upon spasm or irritation. Sometimes there would appear to be a spasm in the neighbourhood of the opening; for a person will have a bellows sound one day and not another. It is said that hysterical women sometimes have this bellows sound, and they have spasmodic affections of various parts.

The Bellows Sound influenced by Venesection.—Frequently, if you take blood away, you

diminish the bellows sound, and even remove it altogether. If you lessen the quantity of blood that has to go through the opening, there will be less obstruction felt, and therefore by bleeding to a certain amount you diminish, or, it may be, entirely remove, the bellows sound. Sometimes in inflammation of the heart this bellows sound is heard; and as you subdue the inflammation, it may never return. In this case, the parts may be thrown into a spasmodic state, just as in the case of the urethra, when that is inflamed. You know that a spasmodic stricture may take place so that no water can pass, and on bleeding the patient, the affection is removed. So I conceive it may happen with the opening of the heart.

Again, the bellows sound will be heard if you bleed a patient too much. You may bleed a patient till you get a sharp pulse, and then you may be led to suppose that inflammation exists, although the person may be blanched like wax. Now when a patient has been thus reduced, I have been told by many that a bellows sound has been heard.

I presume that, in this case, the bellows sound arises from the violent action of the heart: it attempts to drive the blood away faster than it can go with ease. You may, however, have a bellows sound simply from great plethora—there is such fulness of the heart that the blood cannot escape through the opening; and, on the other hand, you may have such a rapid action of the heart that more is attempted to be forced through it than the heart will allow.

Mode of employing the Stethoscope.—In observing these morbid sounds, I advise you to use the stethoscope without the plug. Laennec does not mention the circumstance, but if you examine the sounds of the heart with the plug in the stethoscope, and then take it out, you will generally hear the sounds far louder without the plug. I am quite sure of this; I have proved it myself, and mentioned the circumstance to others, and they have always said they found it to be the case. It is right to examine a patient labouring under disease of the heart with the plug in as well as out; because, when the plug is in the stethoscope, you have a larger surface to strike against.

General Symptoms of difficult Transmission of Blood.—There are of course other symptoms induced by this difficulty to the transmission of blood, than those that are to be learned by the ear. If there be any difficulty to the transmission of blood in the heart, the cavity behind is very much disposed to dilate. The blood not going out with ease, accumulates, and gradually causes a dilatation. This is a very common

circumstance, but it is very curious that you do not have the dilatation by any means always in the cavity immediately behind the obstruction. The auricles are much thinner, you know, than the ventricles, and therefore they more easily become dilated. It is very common in a case of obstruction of the mouth of the aorta not to see the left ventricle dilated, but the left auricle, and even the mouth of the auricle. The effect of an accumulation of blood is frequently felt at a great distance from the seat of the obstruction. Sometimes, in the case of obstruction at the mouth of the aorta, you see the left ventricle dilated, but more frequently it is the auricle. In disease of the mitral valve, you of course cannot expect dilatation of the left ventricle, because it is beyond the obstruction; but you may expect dilatation of the left auricle, or of the right auricle, or even of the right ventricle, behind the obstruction, wherever it may be; but it is by no means an invariable rule, that the dilatation should be immediately behind the obstruction. When there is an obstruction at the left side of the heart, either at the mouth of the aorta or the auriculo-ventricular opening, you will have the obstruction shewn particularly in the lungs. Dr. Wilson, of St. George's Hospital, has mentioned that he has frequently seen what is called "apoplexy of the lungs" after an obstruction of the mitral valve. You will continually meet with an obstruction of the mitral valve without any such circumstance, though certainly it will very frequently happen; but in almost every case you see a general fulness of the lungs. Although you may not see pulmonary apoplexy, you may expect to find a great congestion of blood in the lungs, and this soon shows itself in the whole of the venous system: the obstruction is soon felt beyond the lungs on the right side of the heart. Of course any obstruction on the left side can only act on the system at large. If the blood do not escape from the pulmonary veins easily, it accumulates in the lungs, and therefore it will not pass freely out of the pulmonary artery; then the right ventricle suffers, and all the venous system. The consequence of all this is great fulness of the veins of the neck, frequently fulness of the head, and sometimes fulness of all the veins of the body, and then general dropsy—not only a swelling of the ankles and oedema of that part, but general oedema, which is called *anasarca*, universal dropsy. And then, from the great accumulation of blood in the head, you have headache and drowsiness, and perhaps apoplexy, effusion into the brain and upon the brain, the patient's countenance is blue, his lips pale, and perhaps the nose and eyes look exceedingly

livid. You will, too, in many cases of this description, observe effusion first of all about the eyes. Before the face and neck become œdematous, you will see a puffiness of the lower eye-lid particularly; indeed so striking is it, that many persons have said that it is an invariable sign of disease of the heart. When, however, there is an obstruction to the course of the blood in the chest, you find a puffiness of the lower eyelid.

Besides these, there are symptoms in the heart itself. There is palpitation, a great sense of fainting, and great difficulty of breathing, particularly on motion. In this and all other diseases of the heart, the lungs are very much disposed to fall into a state of chronic bronchitis, so that the patient not only coughs but expectorates, and perhaps expectorates blood, and the difficulty of breathing becomes extreme. The quantity of urine is diminished, and then frequently a great accumulation of blood takes place in the liver, as well as in other parts, and at length there is effusion, not only into the pleura on each side, but into the peritoneum; so that, at last, you have not only œdema, but perhaps general dropsy.

There are two or three other points which I wish to speak of before I leave the subject of diseases of the lining membrane of the heart, and of the peculiarity of the preternatural sound to which a narrowing of the different orifices gives rise.

Preternatural Sounds usually synchronous with the Stroke of the Heart.—The preternatural sounds are heard, of course, far more frequently on the left side than the right, because all diseases of the heart are so much more common in that situation. You will find, however, that you will hear a preternatural sound in an infinitely greater number of instances at the moment of the stroke of the heart than either before or after it. I hardly recollect a single instance of a patient at St. Thomas's Hospital this winter having a preternatural sound of the heart, except at the moment of the stroke of that organ—so much less frequent is it to hear a preternatural sound at the time the auricles allow their blood to go into the ventricles. All cases of a bellows sound, in which there was no real narrowing of the openings to be found after death, occurred at the stroke of the heart; and where it has arisen from a temporary cause, and has gone off again, it has been at the same period, so that the impediment appears to have been at the mouth of the aorta. In the particular case which I mentioned, where a woman had a bellows sound as long as the abdomen was distended with liquor, and no longer, it ceasing when she was tapped, and returning again when the

water re-accumulated, it was heard at the moment of the pulse. By far the most frequent source of it is the aperture leading from the left ventricle to the aorta.

Situation at which the Preternatural Sounds occur.—I need hardly tell you that in general the bellows-sound, when it arises from an obstruction of the mouth of the ventricle, is heard in the lower part of the cardiac region, in the situation of the ventricle; whereas, when it proceeds from a diminution of the opening of one of the auricles, it is heard at the upper part, the auricle being situated above, and the ventricle below. You may sometimes hear the bellows sound not only in the situation where the obstruction exists, but to a great extent: I have heard it frequently in the right axilla, when the heart was not at all enlarged; but frequently it is only perceptible where the obstruction is, and when you hear it in various parts it is always loudest in the immediate seat of its cause. You therefore have it loudest, in general, in the case of the ventricles, at the lower part of the cardiac region; and in the case of the auricles, or auriculo-ventricular openings, at the upper part. When it is on the left side, you hear it loudest in the left half; and when on the right side (where it is rare) at the right part of the cardiac region.

Double Bellows Sound.—You will hear sometimes a double sound, one at the stroke of the heart, and then another immediately after it, like something falling one way and then falling back again directly. I believe that in these cases there is a degree of obstruction to the passage of the blood, so that you have first a bellows sound, and then, as the valves do not perform their duty perfectly, but permit a portion to reflux, you have a second bellows sound. It is by no means a rare thing to hear this double sound, though it is not near so common as a single sound. When the mitral valve is grown up, so that you have merely a circular opening in the middle, of course there is great obstruction, and as the valve does not do its duty well, some of the blood always comes back, and you have a double bellows sound. So in the case of the aortic valves; sometimes the opening is much diminished, and you have a bellows sound when the blood rushes out, and the semilunar valves being corrugated, a portion returns, and you have a see-sawing sound, backwards and forwards.

Bellows Sound influenced by the action of the Heart.—I mentioned that in the case of the bellows-sound which occurs at the stroke of the heart, it is heard loudest when the patient lies down, and sometimes you can hear it only when the patient is in a horizontal position; but when he

is standing up, it is always diminished. You will hear, however, variations in this respect, according to the force of the heart. Sometimes the pulse is very irregular, so that you have a strong thump, then you have a slight one, and then you may have several strong ones. Now in these cases, if there be a diminution at the mouth of the aorta, for example, when the heart acts moderately it gives short strokes, so that the blood is not sent violently through the opening, and therefore it finds its way through pretty well; but when it acts violently, such a torrent of blood is driven against the opening that a great obstruction is felt, and then you have a loud bellows sound. Thus, when you have a bellows sound, and the heart acts irregularly, you will sometimes hear it loud, and sometimes very inconsiderable, according to the quantity of blood driven against the opening, and the degree of obstruction that is felt. If the parts be not very rigid, when the stroke of the heart impels the blood, it may force its way, and the obstruction will not be much felt; but if the parts will not give way, the greater the impulse the more is the obstruction felt.

Purring Thrill.—You will sometimes perceive another circumstance when there are these bellows sounds; and that is, if you lay your hand over the heart, you will find a vibration like the purring of a cat; it is just the same gentle vibration as that which you feel on placing your hand on a cat's back when she is purring. This has been called the *purring thrill*. I do not recollect noticing it in the case of the heart, except where there was a bellows sound, and it appears to arise from an obstruction. It is nothing more than a jar given to the heart by the blood attempting to pass through the obstructed opening. It is by no means generally observed, but every now and then you will feel a vibration in the region of the heart at the moment the bellows sound is heard.

Variations in the Heart's action.—In regard to the degree of the heart's action, it varies both as to force and as to frequency. It has been thought that this indicated the want of a free opening; but you will find that intermissions of pulse, and irregularity of pulse both as to force and frequency, will take place when there is no obstruction; and I do not know the particular state of the heart which gives rise to these variations. You will continually observe this occurrence in old people who never had disease of the heart. It is more frequently observed when there is an obstruction of the mitral valve; but it is by no means a necessary consequence of it.

The tendency of an obstruction on the left side of the heart must evidently be

to produce a small pulse. The heart may act with great violence, but if there be an obstruction at the mouth of the aorta the pulse must be small. If there be an obstruction of the mitral valve, so little blood can escape through from the auricle to fill the ventricle, that the latter has but a small charge to pour forth, and in that case you have a small pulse. Smallness of the pulse may arise just as easily from an obstruction between the left auricle and ventricle, as from an obstruction of the mouth of the aorta; but although it is the effect of these circumstances, yet it is not the result of them alone. You will continually have a small pulse from many other causes, one of which, we shall see presently, is a diminution of the cavity of the left ventricle. If the left ventricle becomes hypertrophied and the cavity diminished, so little blood can be poured into the arteries that you have a small pulse. The heart may beat very violently, but there is so little room for the blood, and so little to escape, when the cavity is diminished, that you have a small pulse.

Necessity of attending to all the symptoms.—There are no symptoms excepting those of the ear to indicate particularly what is the seat of the obstruction, or, indeed, whether there is any obstruction at all; but you will be much deceived except everything be taken into consideration. If you hear a bellows sound, it is not right to infer that there is structural disease of the heart: the sound ought to be heard constantly—not to-day only, but to-morrow and every day—for you to think that there is organic disease of the heart; and even then you ought not to be satisfied of it unless you find other symptoms—such as an enlargement of the heart, a dulness of sound to a great extent, anasarca, great distention of the veins, and so on. The whole circumstances of the case must be taken into consideration. Useful and important as it is to attend to the sounds of the ear, yet it is absurd to depend upon any one of these, and to neglect observing the whole state of the patient—to neglect observing all the general symptoms which medical men notice in the ordinary way.

Influence of diseases of the Heart on the Lungs.—It has been thought that when there was an obstruction on the right side of the heart, the jugular veins were more distended, and the obstruction in the venous system more evidently shewn, than when it occurred on the right. This is no doubt a fact up to a certain point, but it is to be remembered that an obstruction on the left side of the heart must produce the same effects after a time; there will at last be great congestion in the lungs, and in consequence of that there must be an

obstruction to the blood passing on the right side of the heart; then there must be a distention of all the veins, and dropsy. You cannot depend upon these symptoms alone. When you see the veins of the neck distended, that circumstance, considered in itself, will not justify you in saying that the obstruction is seated on the right side of the heart. It may arise from an obstruction there, but there may be a real organic obstruction on the left side. There is, however, this difference—when the obstruction occurs on the right side, there is far less difficulty of breathing than when it takes place on the left. The blood is not at all impeded in its progress through the lungs, the obstruction exists before it goes there; but when the obstruction is on the left side it causes great dyspnœa, on account of its producing congestion of the lungs. But great reliance cannot be placed here, and for this reason—in structural disease of the heart, the lungs are much disposed to become diseased too. From their contiguity to the affection of the heart, they are much disposed to fall into chronic bronchitis; and when that occurs, you have all the signs of difficulty of breathing and of congestion of the blood. Still, it stands to reason that if there happen to be no chronic bronchitis, no affection of the lungs, you will not have dyspnœa when there is only an obstruction on the right side of the heart; whereas, if the obstruction be on the left side, you must expect it.

DISEASES OF THE SUBSTANCE OF THE HEART.

I will now proceed to the consideration of diseases of the substance of the heart, and I think this arrangement will make the matter plain. First we considered the membrane investing the heart; then the membrane lining the heart; and now we will consider diseases of the muscular substance of the heart.

CARDITIS.

The substance of the heart is now and then, but very rarely, the subject of acute inflammation. I do not myself recollect having seen an instance of it, but you will find a most decided case recorded by Mr. Stanley, in the seventh volume of the *Medico-Chirurgical Transactions*.

Symptoms.—The symptoms of this disease would be very similar to those of pericarditis; I hardly think it can exist without that affection being conjoined with it. There has been observed extreme faintness: there is sometimes extreme faintness in pericarditis, but it is not common. In the case of inflammation of the sub-

stance of the heart, however, I think extreme faintness has been noticed—fits, indeed, of syncope. In the case mentioned by Mr. Stanley, there was pericarditis likewise present.

Morbid Appearances.—Now after death, the substance of the heart, in these cases, has been found soft, and black with congestion. The accumulation is so great that the substance of the heart is black. In Mr. Stanley's case, the disease had proceeded even to suppuration, so that there were little collections of pus with which the heart was studded.

HYPERTROPHY—DILATATION.

Hypertrophy.—But although the disease I have now described is very rare, and must be treated like pericarditis, yet chronic inflammation of the heart is by no means rare; on the contrary, it is a common occurrence. I believe that hypertrophy of the heart is in general an inflammatory disease, and my reason for supposing so is, that it is a very common effect of pericarditis. An over-nourished thickened heart has been found under the microscope to be redder than natural, and when the fibres were steeped in distilled water, they imparted greater redness to it than a similar quantity of fibres from a healthy heart. In hypertrophy of the heart, the coronary arteries are very commonly enlarged; and, in fact, hypertrophy must in general be an inflammatory complaint. Excessive nourishment implies an excessive quantity of blood going to the part, an excessive action throughout, and therefore one must suppose that it is more or less of an inflammatory nature. I will not say it is inflammation, but still it appears to me to be of an inflammatory character.

Sometimes this morbid nourishment, thickening, and increased substance of the heart, does not arise from an inflammation of the pericardium, and does not follow it, but supervenes on an obstruction to the exit of the blood from the particular part which is so overgrown. You are aware, with regard to the voluntary muscles, that if any one, or set of them, be particularly used, it grows, and acquires a larger size than it had before. So, in the case of the heart, if from an obstruction existing at the mouth of the aorta it is obliged to make very great efforts to overcome the obstruction, constant palpitation results, and hypertrophy at last takes place. That is one cause of hypertrophy, but it is by no means the general cause. Sometimes an obstruction is not followed by any increased substance; the heart makes what efforts it can, but does not become hypertrophied.

Hypertrophy most commonly of the left ventricle.—That part of the heart which

is more frequently hypertrophied, over-nourished, than any other, is the left ventricle, or rather the walls of the left ventricle. This agrees with the general fact, of disease being more frequent on the left side than the right; but the ventricle of the left side is far more frequently hypertrophied than the left auricle.

Divisions of Hypertrophy.—When the left ventricle is hypertrophied, it is generally firmer than it should be, and likewise redder, but there is a great variety as to the dimensions of the cavity. If the walls be hypertrophied, and the cavity remains of its natural dimensions, this is called *simple* hypertrophy. The walls have become thicker than they should be, but the cavity is not diminished. Sometimes the cavity is decreased; the increase of substance has taken place inwards, so that you have the heart thicker than it should be, and the cavity either correspondingly, or at least diminished. This is called *concentric* hypertrophy. Sometimes, however, the opposite to this occurs; the cavity is enlarged, so that while the heart is over-nourished, the cavities are dilated; and this is called *eccentric* hypertrophy. Thus we have three descriptions of hypertrophy: one, where the cavity remains of its natural dimensions—*simple* hypertrophy; another, where it is diminished—*concentric* hypertrophy; and another, in which the cavity is enlarged—*eccentric* hypertrophy.

Eccentric Hypertrophy.—Now you will, upon a moment's reflection, perceive that you may have a great addition to the substance of the heart, and yet the organ may be neither harder nor thicker than natural, because it may be a case of *eccentric* hypertrophy. If the cavity be greatly dilated, all the additional substance, it may be, is only just sufficient to counterbalance the thinness which would otherwise take place. If a part be not over-nourished at all, but greatly dilated, it grows thinner and thinner in proportion as it is stretched; but if, while it is being dilated, a great addition of substance is made to it, it may lose none of its thickness. Thus you perceive that there may be a case where there is a great addition to the walls of the heart, and notwithstanding that there may be no increased thickness. There is dilatation, and that dilatation of itself would tend to make the heart thinner, and the additional substance may only be just sufficient to counterbalance it; and therefore, in giving a diagnosis that the patient is labouring under hypertrophy of the heart, it does not follow that you are wrong if, after death, the heart proves to be no thicker than natural. If, notwithstanding an enormous dilatation, the heart retains its regular substance, it is to all intents and purposes hypertrophy.

Thickness which the Heart attains.—The thickness which the heart occasionally attains in this disease is very great; sometimes it is not merely double, but treble its natural thickness. It is said that the natural thickness of the left ventricle—which is most frequently the seat of this affection—in an adult is about half an inch; of course there is some variety. I have not noticed the remark any where, but I think we ought not to consider that a heart which is hypertrophied has been thickened during life, merely from observing that the walls are thicker than they ought to be after death; and for this reason: if a part contracts very powerfully at the time of death, and remains in a state of contraction afterwards, of course it will appear thicker. You know that when any muscle contracts, what it loses in length it gains in breadth—in circumference. So, if the heart contract very violently, of course it will become thicker; and that thickness may be perfectly independent of any additional substance. But it stands to reason, that in proportion as it looks thicker, the external size ought to be less; and therefore, whenever you see a heart with its walls very thick, and perceive that the external part of the organ is small, I see no reason to consider that there was hypertrophy during life. I presume that what it has lost in bulk it has gained in thickness, and it is the mere contraction which has given rise to the apparent increased thickness of the walls. At a post-mortem examination you sometimes see the heart very small; but on making a section of the organ, you find that the smallness of bulk is proportionate to the thickness of the parietes; and therefore, in order to say that the heart is hypertrophied, you should not be contented with seeing that it is thicker than natural, but you should also find that the external bulk is of the natural size, otherwise you may be continually deceived. A very violent action may take place in the left ventricle at death, and increase its thickness considerably; but in the same proportion will it lose its breadth.

Circumstances connected with hypertrophy.—With respect to the left ventricle, I had better speak of that in particular first, because it is so much more frequently the seat of hypertrophy than any other part. In *simple* hypertrophy—that is to say, where the cavity is neither increased nor diminished, and in *eccentric* hypertrophy, where there is dilatation as well as increased thickness—the deposition is most frequent about the base of the heart. In the other kind, where the cavity is much diminished, and at the same time the heart is thickened, the addition of substance is the same throughout; the cavity is dimi-

nished in all directions, and the increase of substance is as great at the apex as at the base. When the left ventricle is hypertrophied, you will find the septum particularly thickened, and the columnæ carnæ will be double their natural size.

If there be any dilatation, as well as hypertrophy, the right ventricle (remaining healthy) looks, I was going to say, like a mere little side pocket: it is quite small, and rather behind the left ventricle, not reaching perhaps more than half way down the heart.

I need not remind you that the walls of the left ventricle are far thicker than those of the right; and therefore the ease must not be set down immediately as one of hypertrophy on account of the disproportion between the ventricles. It is well to remember, too, what is the usual size of the heart. It varies in individuals like the face and legs, and every thing else, but it has generally been supposed that it bears a proportion to the fist of the individual: it is so said, but this is a mere rough estimate, because a labouring man will have a larger fist than a very fine gentleman, arising from the more frequent employment of his hand. Still, however, as a general rule, you may say that the heart bears a certain proportion to the fist of the individual—that it is about the size of the fist in different ages; but in a diseased state it will sometimes be even four times larger than that. Another circumstance must also be remembered, which is, that the walls of the left ventricle are not merely thicker than those of the right, but that in infancy they are proportionately thicker than in after life. You might very readily mistake a case of hypertrophy in infants unless you were apprised of this circumstance.

Although the substance of the heart in hypertrophy is generally firmer than usual, yet sometimes it is only of its natural firmness, and occasionally it is softened, but this is toward the latter stages only. The thickening of the walls is not always uniform: occasionally you will see one part of the walls much thicker than another. Next to the left ventricle comes the right in point of frequency of hypertrophy.

Auricles generally dilated—With regard to the auricles, as they are more delicate and thin than the ventricles, their disease is dilatation. You will continually find the auricles dilated, but rarely hypertrophied; whereas the left ventricle is every day hypertrophied, and every day it is both hypertrophied and dilated.

Effects of Hypertrophy and Dilatation—If it so happen that the heart is both hypertrophied and dilated—that is, if it is increased in thickness, as well as dilated—there must, of course, be an enormous ad-

dition of substance. If the walls be increased in thickness, and the cavity is also dilated, you may imagine that the quantity of additional substance is enormous, because there is dilatation, which has a tendency to thin, and yet the walls not only maintain their natural size, but even exceed it. If both ventricles be hypertrophied and dilated, then you have an enormous heart; it attains a frightful size. In this latter case the heart acquires a roundish form, the apex being lost, or nearly so.

Dilatation.—In the case of dilatation, where that is the only thing observable, the heart is generally softened; and where the dilatation bears a great proportion to the hypertrophy, then the heart is generally soft. Dilatation sometimes arises from obstruction; it is not an inflammatory affection, but, from mere obstruction, one cavity or more dilates. Sometimes it would appear to arise from a mere softening of the part, so that it gradually gives way. The dilatation is sometimes attended with such remarkable softening that one cannot ascribe it to any thing else but a morbid softness of the heart.

Auricles temporarily dilated.—The auricles are not only far more frequently dilated than the ventricles, but there is every reason to suppose they are often temporarily dilated; that where an obstruction exists of a temporary nature they become dilated, and when that is removed they go down again; they re-acquire their natural size. The reason for supposing this is, that when the auricles have been much dilated, there has been a dull sound to a great extent at the upper part; and when that has been removed, the natural sound on percussion has been heard again. Such cases of temporary obstruction sometimes occur in the lungs. Occasionally, in chronic bronchitis, and other diseases of the lungs, there will be such congestion that the blood does not get out readily. This is sometimes the case in the auricles; and when it is removed by nature or art, the signs of dilatation have disappeared again.

Hypertrophy sometimes cured.—Hypertrophy itself is sometimes, I believe, cured: being in general of an inflammatory nature, it is sometimes, by antiphlogistic regimen and treatment, altogether removed. Of course there has been no particular tendency to organic disease, and the person has been well treated.

Dilatation of Ventricles seldom if ever cured.—Dilatation of the auricles, it would appear, is by no means a dangerous thing, and is frequently removed, not being a matter of very great importance; but as to dilatation of the ventricles, I should think that they seldom re-acquire their

natural size when they have been dilated. Dilatation of the ventricles usually arises from obstruction at the mouth of the aorta, or some where else, or from a softness of the heart; and of course an obstruction in the heart, of an organic nature, cannot be removed, although you may lessen it; and as to softness of the heart, I cannot think that that has very frequently been removed, though I have reason to think that it has sometimes. I have seen symptoms of dilatation of the ventricle give way when the person acquired strength, but I dare not say that this actually has been the case.

GULSTONIAN LECTURES, 1833.

ON THE FUNCTIONS OF THE ABDOMEN, AND SOME OF THE *Diagnostic Marks of its Disease.*

By RICHARD BRIGHT, M.D. F.R.S. &c.

LECTURE II.

[Continued from page 350.]

ANOTHER very extensive source of information in disease is to be found in the various qualities of the urinary secretion; and the organs on which that secretion ultimately depends are properly included within our present investigation.

This secretion is influenced by the general actions of the body, as well as by causes acting locally upon the kidneys, ureters, and bladder, so that, as a source of diagnosis, the indications derived from the urine go far beyond what belongs to the state of the organs employed in its immediate secretion. Thus we find a most constant and powerful reciprocal action between the brain and nervous system, and the kidneys; between the digestive organs and the kidneys, and between them and the skin; while in some most striking diseases, as in diabetes, it still remains a matter of doubt on what the morbid secretion of the kidney depends; and not improbably the nervous system will be found more closely concerned in this disease than has usually been suspected.

I do not intend to enter into a detailed account of all the indications of disease derived from the urinary secretion—a subject upon which we possess a work from the pen of Dr. Prout, than which one more concise, more accurate, or more philosophic in its character, scarcely exists on any other subject connected with our profession; but still I trust I may be forgiven

if, passing over much of this interesting field of inquiry, I enlarge a little upon one favourite topic,—the indications of disease derived from the albuminous condition of the urine; for I am fully convinced that however great may be the difficulties which present themselves in explaining the dependence of different symptoms, and tracing the links by which they are united, it is a fact that much important disease arises in connexion with those derangements of the kidneys which lead to the admixture of albumen with the urine—a connexion which had not till very lately been the least suspected; and that while it has been the habit of practitioners to read in every sallow or leucophlegmatic countenance an indication of some derangement of the liver, the spleen, or perhaps the uterus, the real cause of the symptoms has often been overlooked; and so completely has even the eye of the anatomist been led astray, that the most confirmed organic changes have passed altogether undetected; and, till within the last five or six years, there are scarcely three recorded instances of a disease which, now that it has been pointed out, fails not to shew itself within the course of every month amongst the casualties of almost every large hospital in the British dominions.

But to come more directly to our subject. In the natural and healthy condition of the urine little or no albumen is to be detected. Many saline ingredients there are, and a large quantity of that peculiar animal matter called urea. The specific gravity of this complex fluid in the healthy state ranges from 1·010 to 1·015 or 1·020, varying in this respect a good deal, according to the time of day when it is passed, and the quantity secreted. Under various circumstances, the secretion becomes remarkably altered in its properties, and amongst these morbid changes, one of the most frequent is the presence of an appreciable quantity of albumen. The existence of this substance may be ascertained by various processes, and it is well not to be contented with one of them alone, as there are several sources of fallacy. One of the most ready means of detecting the albumen, and which is very frequently sufficient, is the application of heat, by taking a small quantity of the urine in a spoon, and holding it over the flame of a lamp or candle. In healthy urine no change follows from this exposure to heat; but if albumen be present, you perceive before the fluid reaches the boiling point, that it becomes opaque, sometimes presenting a milky appearance at the edge of the spoon, which extends inwards till it meets in the centre, and then breaks into a white curd. At other times the whole becomes uni-

formly but slightly opaque, and shortly a multiplicity of bran-like flocculi pervade the whole fluid. When the former of these appearances presents itself before the urine reaches the boiling point, I believe it will generally be found to arise from the presence of albumen; but when the bran-like flocculi are formed, and particularly if it be necessary to continue the boiling, the indication is less certain, for it occasionally happens that where the urea is unusually abundant, a decomposition takes place by the application of heat, and ammonia is formed, which precipitates the phosphates in a form which it is almost impossible to distinguish by the eye from some albuminous precipitates: such, at least, is an explanation of this phenomenon, which has been given me by my friend Mr. Rees, and appears very probable; at all events, the fact of such a deposit taking place when other tests of albumen fail to shew its presence, must point out the necessity of not trusting implicitly to the effects of heat.

The next test, which is easily applied, is the nitric acid, a few drops of which readily throw down the albumen in the form of a precipitate when it exists in urine; but here, likewise, a deceptive precipitate is sometimes formed from the presence of the lithates, or the lithic acid.

On these, and several other points connected with this extensive and interesting subject, I have lately had great assistance from the intelligent and zealous co-operation of three of my young friends and pupils, Mr. Barlow, Mr. Tweedie, and Mr. Rees. These gentlemen have found, from experiments made upon the urine of two hundred and ninety-six patients, taken promiscuously, in Guy's Hospital, that forty-four, that is, fifteen per cent. were coagulated by heat; that thirty-seven, or twelve and a half per cent., gave precipitates with nitric acid; and twenty-six, or eight and four-fifths per cent., gave precipitates with both.

Eighteen cases, then, gave precipitates with heat, but none with nitric acid, which precipitates were readily re-dissolved by the addition of the nitric acid. These were, therefore, so many cases which could not have been albuminous, and would have deceived had the single test of heat been trusted: they were cases in which the phosphates were precipitated by ammonia generated during the decomposition of the urea. Eleven cases gave precipitates with nitric acid, though none by the application of heat; and in these cases heat always re-dissolved the precipitate, and an additional quantity of nitric acid sometimes did the same. These were cases in which the turbidity arose from the presence of the lithates or lithic acid. From this statement it is quite obvious that we ought not

to place dependence on either of these tests singly; but when employed together, they are, I believe, to be trusted; and wherever a decided precipitate occurs from heat which is not re-dissolved by dilute nitric acid, we may fairly infer the presence of albumen. Oxymuriate of mercury is, indeed, a very nice test of the presence of albumen; but it very frequently throws down precipitates from urine, which may easily be mistaken; and the acetic acid, with the ferro-prussiate of potash, which is one of the most delicate and least exceptionable tests, is not quite so easy of application as either heat or nitric acid. These, therefore, upon the whole, when taken together, appear to me the most applicable tests in the greater number of cases.

We are told that many circumstances acting on the constitution, and even slight errors in diet, will often suffice to produce the albuminous condition of the urine, and probably this may be the case, though the observations which I have just stated, on the fallability of our tests, when they are not brought to support each other, render it possible that many of the instances in which this state of urine has appeared to arise from such trivial causes, have been deceptive; but where the albumen is proved to exist, however slight the tendency to this condition may be, I own I always look upon it with anxiety, and the confirmed derangement I always view with dread.

It is believed by some late observers that, provided the specific gravity of the urine be not notably diminished, we have much less reason to dread the result; and this is probably in many cases the fact, because the urine, though it become turbid, does not actually contain albumen, but some other ingredient, which adds to its specific gravity. It was remarked by my two friends, Mr. Barlow and Mr. Tweedie, in the extensive investigation to which I have been referring, "that with regard to the specific gravity, it was so variable not only in different patients, but in the same patient at different times, that they found it very difficult to draw any satisfactory conclusions from it. It was found to vary from 1.005 to 1.029. The urine of the lowest specific gravity was albuminous, but several specimens of albuminous urine had specific gravities above the average. That passed early in the morning was generally from 1.020 to 1.025; and that in the middle of the day about 1.015. Those specimens which afforded the phosphatic precipitate upon the application of heat, had invariably high specific gravities." In connexion with this subject, it is worthy of notice, that when the urine of a patient was found to be truly albuminous, urine obtained from the same patient,

within a few days, was so likewise; whereas this constancy was not found with regard to patients whose urine gave the phosphatic precipitate. It appears by no means improbable, that some of those cases in which apparent coagulability has existed, and the specific gravity has been higher than usual, have not really been cases of albuminous urine, but that the precipitates thrown down were derived either from the phosphates or the lithates.

In proportion as the disease continues, or is confirmed, the urine loses those properties which it derives from the presence of urea; but what is still more remarkable, and what seems in some way to account for the general derangement and suffering of the constitution, is the fact that the urea now becomes demonstrable in the circulating mass; the blood becomes impregnated with that substance, or at least the elements of which it is formed are so abundant or so arranged in the blood, that the urea is generated in the chemical processes used for its detection: so that in the case of a young woman who was two or three years under my observation, with albuminous urine, Dr. Benjamin Babington found no less than fifteen parts in a thousand parts of the serum of the blood to be chiefly urea, though somewhat impregnated with other substances. Now whether the urea, being separated by the kidney, is thrown back upon the system, or is retained in the blood till, in itself or in its elements, it becomes discoverable in that fluid, it is plain that what appears to be the great office of the kidney—the depuration of the blood—does not take place; and we must ever bear in mind that there is no emunctory of the body more indispensable in its action than the kidney: for while even the liver may be most extensively destroyed by disease, and while its ducts may be perfectly obstructed for weeks before the consequences are fatal, it is but seldom (and then only under some very peculiar forms of disease, as cholera) that the patient can survive even a few days the suppression of the urinary secretion.

When the kidney has for some length of time been affected with that morbid condition which is marked by the secretion of albuminous urine, and death has taken place, we usually find certain organic changes, very marked and very generally affecting the substance of the kidney, but varying in some degree in different individuals. The healthy kidney allows its tunic to be stripped off with a tolerable degree of facility, and then presents a perfectly smooth and shining surface, of a general red colour, with an indistinct but regular marking, not very unlike the surface of the liver, derived from the fine secreting struc-

ture; and when an incision is made through the kidney, its whole interior presents a light-red colour, little differing from the outside. If death take place shortly after the deranged secretion has been set up, there will probably be little or no morbid appearance, or there will be sanguineous congestion, more or less marked; but after it has continued long, a quantity of opaque white matter will be discoverable, mingled with the natural texture; and on cutting the kidney open, this white deposit gives an unnaturally light colour to the kidney. Sometimes the kidney is large and soft, still pretty smooth upon the surface; at other times raised into projections, and much variegated and mottled, still soft and large. But there is another form which the kidney assumes, which either arises from another modification of the action or shews a more advanced stage of the same disease. The kidney is small and contracted; the whole surface is rough, almost scabrous; the texture is of a semi-cartilaginous firmness, and the tubular portion is drawn towards the surface of the organ. Such are some of the chief modifications of the diseased structure presented by the kidney, in connexion with that diagnostic test which we are now considering.

One of the most frequent circumstances which calls our attention to this condition of the urine, is the existence of anasarca, which is a common attendant upon the acute attack of the disease; and though it is possible that in many cases the coagulable condition of the urine may have existed previously unobserved, and have been but the predisposing cause to the attack of anasarca, yet, judging from the circumstance that the anasarca which follows scarlatina, the subjects of which are often young persons of apparently unbroken constitution, is frequently of this character, and is almost always accompanied by an obvious derangement of the kidneys, attended by more or less tendency to hæmaturia, I am inclined to suppose that the anasarca is an immediate consequence of the derangement of the kidney. Thus, then, the common history of such cases of anasarca will be found as follows. An intemperate course of life, or some such cause, has predisposed the kidney to suffer. The patient has, in this state, been exposed to vicissitudes of temperature; the irritable kidney has immediately sympathised with the skin, and morbid action has been induced in that organ; the balance of absorption has been destroyed, and serous accumulations have taken place. In scarlatina the skin has derived peculiar susceptibility from the previous exanthematous eruption, and the sympathy between the skin and the kidney is a well admitted

fact. If the kidney have previously been healthy, and if the patient be seen early, and antiphlogistic remedies actively employed, the morbid action subsides; the urine ceases to be coagulable, the anasarca disappears, and the patient is perfectly restored, without any organic lesion of the kidney. If, on the contrary, the kidney have previously been greatly deranged, or the severity of the present attack have been great, or the application of remedies tardy, the acuteness of the attack may be moderated—the anasarca may disappear—but the urine may remain coagulable; leaving the patient subject to relapses of anasarca, and otherwise in a condition very little prepared to withstand disease. That anasarca is by no means a necessary concomitant of albuminous urine, is proved by the fact that, of the twenty six cases which were found by my young friends, in their examination of 296 patients, to be coagulable both by heat and nitric acid, and were fairly considered to be albuminous, fifteen had no symptoms of anasarca; and the same investigation shews, were it necessary to shew the fact, that anasarca is not necessarily accompanied by albuminous urine—for three, at least, of the cases they examined, had anasarca without the symptom of which we speak.

From several cases which have come under my observation, I think it probable, that even after severe attacks of this renal disease, and when it has gone on to the disorganization of the kidney, the morbid action may cease, and the organ return to its natural function in a great degree; or at least its action may be so far changed that no albumen is secreted: so that this circumstance may cease to afford the requisite information, though the morbid change remains. In cases of this kind it is necessary to examine the urine often, for although it may cease to be albuminous for a day or two, as the result of medicine or other causes, yet will it probably, upon some slight exacerbation, resume its former qualities; and if it does not, there are other indications to which we may direct our observations, and which will render it probable that the disease is masked or suppressed for a time, rather than overcome. The general leucophlegmatic aspect—the tendency to anasarca swellings in the face and ankles—the occasional hæmaturia—the pain referred to the kidney—the frequent headache,—are all symptoms which occur when the kidney is left in a state of disorganization.

I have not only had many instances within my own observation, of the cessation of the secretion of albumen for a short time under the use of remedies, when there has been reason to suppose the organic disease to be confirmed, but I have had two or

three very striking cases communicated to me by my friends. In April 1830, Dr. George Burrows brought me a kidney in the most confirmed state of granulation, so completely pervaded with deposit as to have lost all the structure of the cortical portion, and to have put on a marked scabrous character externally. This was taken from a patient who had been in St. Bartholomew's Hospital for a fortnight only, with confirmed anasarca; and in addition to the disease of the kidney, the heart was greatly enlarged and otherwise diseased. In this case, during the whole fortnight which preceded death, the urine had been very scanty, and perfectly limpid—neither acid nor alkaline, and had shewn no tendency to coagulate by heat. Within these few months Dr. Watson afforded me an opportunity of seeing the kidneys of a patient dying anasarca in the Middlesex Hospital, which I should not hesitate to pronounce well-marked specimens of the organic change produced by that disease, which is so often accompanied by the secretion of albuminous urine; but this state of the urine did not exist during the time he was under Dr. Watson's observation, and the action of the kidney was so far annihilated, that it was only by gin and stimulating diuretics that a scanty secretion was obtained: in that case, likewise, the heart was much enlarged, without any sufficient cause being discovered.

It is the occasional occurrence of facts like these which naturally excites a doubt in the mind as to the accuracy of the deductions which have been drawn; but although these facts may diminish the value of the albuminous state of the urine, as affording a perfectly unerring source of diagnosis, when observations are made on the secretion embracing only a short period, and more particularly that short period which precedes the fatal termination, they do not shake my confidence in the persuasion, that a great deal of general derangement of the system, and a large class of dropsies, depend on diseased action in the kidney, which diseased action betrays itself particularly in its early stages, but likewise from time to time in all its stages, by the coagulable quality of the urine, and leaves the kidney not unfrequently quite disorganized. I have now witnessed so great a number of cases, in which no other disease could be traced after death but the disorganization of the kidney, to which we might look as the probable source of anasarca, and in so large a proportion of such cases I have found the urine coagulable, that my conviction is complete as to the existence of some decided connexion between the three facts—anasarca, coagulable urine, and diseased function going on to

diseased structure of the kidney. How these facts are connected, or what necessary dependence the one may have upon the other, it is indeed difficult to point out; and some might suppose that we are rather perverting the order of events when we speak of the condition of the kidney as causing the anasarca; whereas, is it not possible that the cold or other morbid cause, acting on the system, produces in some other way the anasarca, and then, the absorbents still acting, the anasarcaous fluid passes off by the kidneys? To this I would only say, the solution does not appear impossible; but when I know that the same coagulable state of urine which exists during the presence of the anasarca—when it is possible that the albumen is thus supplied to the kidneys, or that the unnatural fluid supplied produces the morbid secretion—often exists when no anasarca has shewn itself, and very often continues for months and years after the anasarca has subsided, I do not feel inclined readily to assent to this solution of the facts; and besides, how would this explanation account for the disappearance of the urea from the fluid secreted by the kidneys?

There are some other curious coincidences which often arise in the progress of these cases, amongst which is the very frequent occurrence of affections of the heart, under a variety of forms; but in several instances the affection has been hypertrophy and dilatation of the left ventricle, attended sometimes by less valvular disease than might be expected to account for the derangement of the heart. In the case to which I have just referred from Dr. Watson this condition of the heart shewed itself, and a considerable enlargement of the heart was likewise observed by Dr. George Burrows.

In many of the cases of this disease we find the liver deviating from its natural appearance; sometimes, indeed, it is decidedly diseased, for the existence of the disease of which I am speaking by no means precludes the possibility of other visceral derangements; on the contrary, the very habits which pave the way for the disease of the kidneys tend greatly to derange the liver in particular. But the most frequent variety in the aspect of the liver which I have observed in these cases, has been that spotted, mottled appearance, which arises from a very slight alteration of colour in the acini, and a degree of sanguineous congestion in the interstitial substance, thus producing a stronger contrast in the colours of these structures than is natural. These slight indications of derangement are, however, comparatively rare, and much more frequently have I found the most perfect specimens of

healthy liver in patients with coagulable urine, even where this symptom has been accompanied by anasarca; so that I am convinced the derangement of the liver is but a casual, and not a necessary coincidence.

By a comparison of 48 cases, I find that in 18 the liver was perfectly healthy, and in many of them in a most unusual degree free from the slightest trace of disease; and in 5 more cases, the state of the liver has not been stated; probably, therefore, it was not diseased: nor does this immunity seem to have any reference to the soft or the scabrous condition of the kidney; for, of the 18 cases of healthy liver, 9 were soft, and 9 hard. Amongst the remaining cases, 7 were healthy, except as regarded a slight injection of the substance intervening between the acini, of which 4 were connected with soft, and 3 with hard kidneys. In 10 cases, the liver was slightly granulated; in 1 it was fatty, connected with the soft state of kidney; and in 6 cases only, besides this 1, was the structure of the liver very manifestly diseased; and in 4 of these cases the kidneys were hard, in 2 soft.

In many cases we find evident marks of old or of recent inflammatory affection of the serous membranes; these, however, we frequently find altogether absent. The fact is, as I believe, that during the time the urinary secretion is so unhealthy, a very unusual tendency to inflammatory action exists, and in no part does it show itself more frequently than in the serous membranes. Thus, in 31 out of 48 cases, a notably morbid quantity of serum was effused into the cavities of the chest; while in 15 cases, adhesions more or less extensive existed between the lungs and the pleura costalis, or other marks of decided inflammatory action were to be traced. In 15 cases, effusion had taken place into the abdomen; and in 6 cases evident marks were found, either of recent or old peritoneal inflammation and adhesion. The effusion into the chest has been more frequent, in the proportion of 18 to 13 in the more advanced cases, when the kidneys have had their structure most completely destroyed, than in those which we presume to be less advanced, and where the kidneys retain their softness and pliability.

The head is likewise very liable to suffer under this affection, for seldom do we find this disease without a frequent complaint of headache, and sometimes of giddiness; and in a great many instances coma and apoplectic symptoms supervene, which, on examination, sometimes prove to have been connected with the effusion of blood, and sometimes of serum. In a small proportion only of the forty-eight cases of which I have the records, was the head examined; yet from amongst them I

find eight in which more or less effusion and thickening of the membranes of the brain was observed. Not unfrequently no such obvious cause of the symptoms can be discovered, even when examination is most carefully conducted; in which cases it is not improbable that the altered and deteriorated nature of the blood is one of the causes of the symptoms. In cases of great urinary difficulty, symptoms of this kind are not uncommon, and there is reason to believe that the urea in the blood may be the cause of them. A very interesting case lately occurred at Guy's Hospital, under the care of Mr. Morgan, in which a patient, after being long affected with severe disease in the urinary passages, secreted very little urine, and fell into a state of complete coma. As he lay in his bed, with his countenance pallid and bloated, he had all the appearance of a man dying under serous apoplexy; yet when he died, there was no overwhelming accumulation of serum, but Mr. Rees found from two or three drachms which were collected a result which led him to conclude that urea was present; and Dr. Prout, who was so kind as to examine, at my request, the crystalline matter thus obtained, thought, as far as he could judge from the very small quantity I gave him, that it consisted of nitrate of urea. I do not know whether the urine passed by this patient was albuminous, but both the aspect of the man and the appearance of the kidneys rendered it very probable.

In reference to surgical disease, I conceive that the albuminous quality of the urine is a consideration of much importance. The healing process is decidedly less active; and under some severe operations, the powers of the system are much less adequate to bear the immediate shock, or withstand the irritation, attendant upon the subsequent progress of repair. It has occurred to me to know that in two or three instances where the operation of lithotomy has unexpectedly terminated fatally, the granulated condition of the kidney has been discovered; and it is very necessary that we should distinguish between these peculiar forms of degeneration and deposit in the kidney, and the condition which the organ acquires in persons disposed to tubercular disease, or those in whom great irritation of the kidney is induced by the formation and presence of calculous matter, in both which cases the tendency is to suppuration, and not to induration and contraction.

It cannot be disputed that the proof which we derive from pathological investigation of the frequent co-existence of undoubted marks of pleuritic, and even sometimes of pulmonary inflammation, with coagulable urine and the diseased

kidney, affords a rational ground for argument in favour of the supposition that the affection of the kidney is but secondary. We have, however, no evidence whatsoever, derived from symptoms, in the commencement of a very great majority of these cases that any thing like thoracic inflammation exists; while, on the other hand, we know that inflammation of all the serous membranes, shewing itself by its own well-marked symptoms, is very apt to come on in the advanced periods of this complaint; besides which, we are not to suppose that in a constitution in which anasarca has been long established, every effusion into the cavities is an unequivocal indication of inflammatory action in the part in which it is effused.

With regard to the affection of the heart to which I have referred, I have occasionally been able to trace the gradual approach and increase of the hypertrophy coming on many months after the albuminous condition of the urine has been established; and it is not improbable that the various evidences of cerebral disturbance which follow in the train of the chronic derangement of the kidney, though in part depending on the urea circulating in the blood, may in some cases be owing to the disease first induced on the central organ of circulation; thus affording another curious illustration of the connexion and the dependence which exist amongst the different functions of the body.

Having said so much upon this particular form of the urinary secretion, it may be thought wrong that I should pass over others scarcely less important; some of which point out the existence and subsidence of febrile action—some of which accompany or even precede the other symptoms of jaundice; some of which demonstrate the prevalence of certain morbid diatheses disturbing the whole frame, and frequently leading, as one of their many evil consequences, to the formation of calculi of various characters and composition. Other states of the urinary secretion I might with propriety dilate upon, as marking the existence of inflammation, of ulceration, of abrasion, or of malignant disease in the kidney itself; or I might claim your attention to those changes which the urine undergoes as it passes through the bladder; its natural properties heightened by being retained, its alkaline parts increased, or the mucus of the bladder copiously mingled with the secretion of the kidney. But although, on a favourite subject, I may have spoken too much at length, I will not longer detain you on the points of diagnosis connected with the urine; only reminding you, that in the case of the kidney, as in that of the intestines, but in a much less degree, the

appearance of the secretion may be changed by the character of the ingesta, or the nature of the remedies exhibited; some of which are very speedily recognized in the urine.

The circumstances connected with the catamenial and the vaginal discharge also call for our attention in the investigation of abdominal disease. Its profuse or its deficient quantity often the foundation of those neuralgic ailments which cast obscurity upon the diseases of the abdomen—dysmenorrhœa, the cause of vomiting and purging—the imperforate vagina, leading to tumor from accumulation within the uterus—and leucorrhœa, accompanied with a host of pseudo-abdominal symptoms. Never, indeed, can we see the doctrine of sympathetic disease more fully illustrated than when we study the symptoms which uterine irritation throws around it, as if to mislead us from the source of diseases, but more fitly viewed as calculated to prompt our ardour in the investigation of the obscure portions and the more intricate relations of our frame.

TREATMENT OF HOOPING-COUGH.

To the Editor of the Medical Gazette.

North Shields, May 20, 1833.

SIR,

My attention having been directed a good deal lately to whooping-cough, I am induced to send you the result of my observations, if you think them worthy a place in your excellent Gazette. I have no new remedy to bring forward; but I think the success of the treatment depends upon the stage of the disease in which any particular remedy is employed; and hence, perhaps, arises the multiplicity of medicines occasionally used in the treatment of that disease, and also the disappointment which is often experienced in the effect of such medicines. But I have found the success in conducting patients safely through the complaint, and also of shortening its duration, mainly to depend upon preserving them completely from atmospheric influences. It appears to me that the disease may be divided into three stages, which I shall designate the inflammatory, the congestive, and the spasmodic. The first, or inflammatory stage, commences very much like a common catarrh, with a short dry tickling cough, discharge from the eyes and nose, and generally a dull pain in

the head, with a sense of weariness and listlessness, and not unfrequently a regular attack of pyrexia; and where this is not distinctly marked, the patient, I believe, always feels chilly for the first two or three days, the pulse being slow and depressed; after which time there is an increase of temperature on the surface of the body, and a somewhat quickened pulse, the tongue being furred, and the bowels for the most part torpid, the appetite impaired, and some thirst; but all these symptoms are sometimes so slight as to excite little or no attention; and yet I believe this stage to depend upon an inflammation of a sub-acute nature pervading the air-passages, which, by cold or other exciting causes, becomes of a more active character, assuming the form of either croup or bronchitis, by which many children are cut off, without its being suspected that it has its origin in the contagion of whooping-cough; but such instances will always be found to be of frequent occurrence when that disease is prevailing in a neighbourhood.

In the second, or stage of congestion, the fever has generally passed over, or, at least, only returns at intervals; the tongue often gets clean, the appetite returns, and not unfrequently becomes inordinate, copious expectoration takes place, the cough coming on in paroxysms, often attended with vomiting, and the hoop is completely formed. The face becomes puffed, the eyes blood-shot, and bleeding from the nose and ears is not unusual; the patient often complains of intolerance of light, and the hearing becomes impaired. In this stage of the complaint, convulsions and water in the head not unfrequently supervene.

In the third, or spasmodic stage, which is often a very protracted one, all the more urgent symptoms decline, leaving great debility and emaciation, and a pale exsanguined countenance; but the cough still continues, and the hoops occur perhaps even more frequently in each paroxysm; but the face no longer becomes purple, nor is vomiting any longer a usual accompaniment of the coughing fits. The expectoration also is much diminished, and it is not difficult to distinguish that the disease has changed its character, and has become one of debility, and perhaps of habit established in a weakened system.

Treatment of the first stage.—That

part of the treatment on which I place the greatest importance, and upon which the efficacy of the remedies in a great measure depends, is the confining the patient to a single room, which is to be maintained at an equal temperature, keeping him on a strictly antiphlegmatic diet, and administering such medicines as will keep up a moisture on the surface of the body, and also excite the action of the kidneys, which is generally very deficient. Leeches should also be applied to the chest every two or three days, and the bowels kept freely open, and the warm-bath used every evening before going to bed. By these means the bronchial affection is generally soon relieved, and the second stage comes on in a very mitigated form.

Treatment of second stage.—Precisely the same plan to be pursued, except that now leeches are to be applied to the forehead or temples, either daily, or every two or three days, according to the severity of the cough. The purging, the warm-bath, the equal temperature, all to be continued, and farinaceous diet, with milk, to be taken; and if the pulse is quiet, and there is no thirst, a few grains of ext. conii, and ext. hyoscyami, added to the saline mixture, will have a very beneficial effect in relieving the cough.

Treatment of the third stage.—The best remedy I am acquainted with is change of air; at the same time, the system should be invigorated by a moderate use of animal food. The hydrocyanic acid sometimes acts like a charm in this stage of the disease. The carbonate of iron is also an excellent remedy; and in very protracted cases I have used sea-bathing with the best effect.

I remain, sir,
Your obedient servant,
EDWARD GREENHOW.

we beg to offer for insertion in your excellent journal the following remarks on the variation of urine from its normal standard, chiefly compiled from the seventh volume of the elaborate work of Berzelius, which has been just published in Paris. Should this meet your approbation, we propose to transmit to you some observations on the blood, particularly on the serum of that fluid.

We are, sir,

Your obedient servants,
R. H. BRETT.
GOLDING BIRD.

Gay's Hospital, June 10, 1833.

During the first period of fevers, the cutaneous transpiration being obstructed, the urine becomes more aqueous than in its healthy state: when the heat of the body increases, with acceleration of pulse, the urine becomes deeper coloured, without, however, letting fall a deposit, while its acid reaction diminishes, and at last nearly or entirely disappears; it is then rendered turbid by the addition of bichloride of mercury, which does not happen when the acid is present. As the disease advances the urine becomes more saturated, and is then rendered turbid by a solution of alum. When albumen is secreted more copiously, it is troubled by nitric acid and heat. When the fever ceases, as, for instance, on the seventh day, the free acid suddenly re-appears, the colour of the urine deepens, and it forms a deposit by cooling. This deposit is not an evacuation of morbid matter, but is merely a combination of red colouring matter, with uric acid or urate of ammonia, and perhaps nitric acid, in an unknown state of combination. In intermittent fever the urine presents these phenomena at each paroxysm, and then the deposit assumes a carmine tint. During slow nervous fever, there is constantly formed an abundant deposit of uric acid, containing little colouring matter; the urine then contains an excess of the phosphates and a deficiency of urea, the other ingredients being in their normal proportion.

In anasarca, which is generally the result of debility of the whole system, serum is effused into the urinary passages; hence the urine appears albuminous, and is troubled by bichloride of mercury, although much free acid may be present. After a short time, the

ON THE CHEMICAL CONSTITUTION OF URINE IN VARIOUS DISEASES.

To the Editor of the Medical Gazette.

SIR,

A KNOWLEDGE of certain of the secretions and excretions belonging to the animal economy being now generally admitted to be of the utmost importance in the scientific treatment of disease,

kidneys appear to secrete an albuminous fluid, which occasions the urine to be precipitated by a solution of alum, nitric acid, or heat. As the albumen increases in quantity, the urea diminishes, and finally disappears altogether. These phenomena likewise appear in chronic hepatitis, dyspepsia, and towards the close of pulmonary affections, especially during the last stage of hectic fever.

During severe vomiting, whether from scirrhus of the stomach or otherwise, the urine is frequently turbid, and has a milky aspect, letting fall a white deposit, which, when collected, appears mucilaginous, and by desiccation becoming first yellow and translucent, then white and pulverulent; by affusion of water it resumes its mucilaginous form; pure potass dissolves out of it mucus, leaving a residue of phosphate of lime. Hydrochloric acid dissolves the latter and renders the mucus transparent, which also dissolves by digestion. This state is generally accompanied with alkaline urine, arising from the presence of the carbonates of soda and ammonia, diminished quantity of uric acid, and an excess of urea. In gout the urine is usually very acid, except during the paroxysms, when it becomes alkaline or neutral; uric acid is always present in considerable excess; the deposit is also abundant by cooling.

In jaundice the urine appears yellow, from an admixture of biliary matter; and on the addition of nitric acid, a play of colours is generally produced. Hydrochloric acid renders it green or brown, according to the state of modification in which the biliary matter exists. Sometimes orange-yellow flocculi are deposited: these are soluble in caustic potass, and give the usual reaction with nitric acid, in partial hepatic obstructions, when no discolouration of the skin has appeared: the bile, by passing through the lymphatic vessels of the engorged parts, enters the circulation, and may be detected in the urine by evaporating a portion of the latter, digesting the extract in alcohol of specific gravity $\cdot 833$, and letting the tincture evaporate to dryness. The addition of nitric acid will then produce the change of colours—viz. green, blue, violet, and yellow—which characterizes the colouring matter of bile. In spasmodic and hysteric affections, the urine often becomes limpid and colourless, being,

indeed, merely a solution of the urinary salts, deprived of almost every particle of organic product.

In diabetes mellitus, an immense quantity of sugar is secreted. At the first access of the disease, the only symptoms are copious emission of urine and diminished appetite; the cutaneous transpiration is obstructed, and the urine is supplied with water from all the fluid ingesta. The specific gravity is often as high as $1\cdot 050$; as the sugar increases the urea diminishes, and at last totally disappears: colour pale-yellow, taste sweet, odour like that of skim-milk; the inorganic salts are present in their natural proportion, being merely diluted with a larger quantity of fluid. Towards the close of the disease, when hectic fever makes its appearance, the urine becomes albuminous, and now passes spontaneously into the alcoholic fermentation; the quantity of urine expelled increases to an enormous amount. We may calculate by the following formula the weight of the dry extract in solution in the urine, and of course the quantity daily expelled. A pint of urine, specific gravity $1\cdot 020$, leaves by evaporation $382\cdot 4$ grains of dry extract; which weight increases in the proportion of $19\cdot 2$ grains for each unit of specific gravity, until the latter amounts to $1\cdot 050$; so that if we have a patient voiding urine of specific gravity $1\cdot 021$, we can determine the weight of solid matter present in his urine by making this calculation, $382\cdot 4 + 19\cdot 2 = 401\cdot 6$ grs. in every pint. When diabetic urine is evaporated to dryness, and alcohol digested on the residue, the sugar and extractiform matter are dissolved; this solution, by repose, leaves either granular crystals, like grape sugar, or merely a honey-like mass. We are ignorant whether this difference is owing to a diversity of saccharine matter, or to the presence of a deliquescent matter, which prevents its crystallizing. Sugar has been sought after in vain in the blood of diabetic patients: indeed this disease appears to be seated solely in the kidneys, which convert almost every portion of organic matter arriving in those viscera into sugar. When a favourable change takes place urea re-appears, and a quantity of albumen makes its appearance in the urine.

M. Meisner, who has paid great attention to this subject, gives the following quantitative analysis of three

specimens of diabetic urine, taken from the same patient at different periods :—

	1.	2.	3.
Mattersolublein ether, urea lactic acid, lactate lime, extracti- form matter ..	0.34	0.33	0.65
Mattersolublein alcohol, diabe- tic sugar, ex- tractive matter, and salts.....	7.06	3.46	5.78
Mattersolublein water: extrac- tive matter and salts	1.37	3.44	0.99
Vesical mucus, subphosphate of lime, and traces of pe- roxide of iron	0.34	0.31	0.46
Water	91.19	92.46	92.10

In diabetes insipidus no sugar is found, but there is present in the urine a matter similar to that obtained by digesting alcohol on an aqueous extract of muscular fibre: no ultimate analysis of this matter has been as yet made.

CASE OF LITHOTOMY—LARGE CALCULUS.

To the Editor of the Medical Gazette.

SIR,

I HAVE to request that you will insert the following case of lithotomy in your journal, as I trust it will be found sufficiently interesting, independently of the size of the stone.

In March 1832, I was requested to visit Mr. David Lawrence, of Winchelsea, with the view of performing the operation for the stone. Upon my arrival and inquiring of the patient how long he had been troubled with the complaint, he said ever since he was twenty years of age, and that he was now seven-and-forty, which unpleasant account was strongly corroborated upon my introducing the finger, *per anum*, to examine the state of the prostate, when so very large a stone presented itself as to leave me in doubt whether there would be sufficient room between

the ischia to admit of its passing, unless I had recourse to the operation by the rectum, and I had no apparatus with the view of breaking the stone with me, except the common forceps. I, however, determined on the lateral operation, resolving to render it bilateral, by dividing the right side of the perineum with the scalpel, also, if urged by necessity. However, by means of a pretty ample incision, and using a double-edged gorget, I succeeded in extracting the stone, which weighed six ounces and a quarter, and have the satisfaction to add, that my patient has done perfectly well. It is hardly to be imagined how little pain or inflammation succeeded the operation, which perhaps may be best explained by the bladder having been so long accustomed to pain and irritation. But a still more remarkable circumstance is, that, however long this man might have had the stone in the bladder, he had continued in an active course of business, which occasioned him to ride as well as walk, with very little interruption, till about seven weeks before the operation, and between Christmas and the beginning of January he informed me he walked fourteen and fifteen miles in one day without any inconvenience. This must, therefore, have been but a few weeks before the operation. About four years ago, in consequence of his being worse than usual, he consulted Dr. Wilmot, of Hastings, who first informed him that he suspected stone in the bladder; but he was not sounded till September 1831, when he went to London, and consulted Mr. Lawrence, of St. Bartholomew's Hospital, who detected a stone, and advised an operation, which he submitted to, as already stated, in March following.

Your obedient servant,

T. HODSON.

Lewes, May 20, 1833.

REMARKS ON THE CLAIMS OF EDINBURGH PHYSICIANS.

To the Editor of the Medical Gazette.

Edinburgh, June 3^d, 1833.

SIR,

As you have published the memorials of different public bodies on the subject

of the proposed alterations of the Apothecaries' Act, and professed your desire to have the subject fairly and dispassionately discussed in your pages, I am induced to request that you will insert this letter, and the accompanying memorial, presented by the Senate Academicus of this university to his Majesty's Secretary of State,—in order that the grounds on which this University have rested their application may be generally known to the profession.

In the observations which you have yourself made on this subject, you seem to have regarded the Apothecaries' bill, as it now stands, to be defensible chiefly on two grounds:—1st, That in Scotland, from whence the chief remonstrances against the bill proceed, exclusive privileges, and a still more illiberal character than those conferred on the Apothecaries by the bill, are possessed by different medical corporations; and 2d, That unless the Apothecaries' Company retains the exclusive privileges conferred by the bill, they will be unable to carry on prosecutions against quacks or unqualified practitioners, and the public will lose the security, which they now possess, against such persons.

On the first of these points, I cannot help expressing my surprise that you should not have been already informed, that the exclusive privileges alluded to, and nominally possessed by the Colleges of Physicians and Surgeons in Edinburgh, have been long since completely obsolete, no prosecutions having been instituted by either of these bodies within the memory of man, and many individuals being fully engaged in practice, in the districts nominally under their jurisdiction, who have no connexion with these Colleges, and never underwent examination before them, or in any manner recognized their authority. The Faculty of Physicians and Surgeons in Glasgow have, of late years, exercised a power of examination over practitioners settling in four of the counties of the west of Scotland, but never any power of enforcing apprenticeship to members of their own body; and I am assured that they have intimated to government their willingness to relinquish any such power, over Licentiates of the Company of Apothecaries, if the projected alterations of the bill shall be made. Even in that district, however, on examination, and in all other parts of Scotland, without exa-

mination, the Licentiates of the Apothecaries' Company in London are as much at liberty to engage in practice as in any part of England; and all that is asked, in the petitions on this subject, is, that persons licensed by the Universities, and other recognized schools in Scotland, shall have the same facility to practise their profession, in the manner they may judge most conducive to their own interests, in England, as those licensed by the English school practically possess in Scotland. If it were thought necessary to protect Licentiates of the English schools, against the privileges of the medical corporations in Scotland, by express enactment, I need hardly say that no objection to such a law would be made here.

On the second point above stated, I take the liberty of observing that it seems a strange proposition, and almost a libel on legislation, to assert that it is impossible to contrive a law which shall give the Apothecaries' Company power to prosecute persons, *less* educated than their own Licentiates, for practising and dispensing medicines, without, at the same time, giving them power to prosecute men better educated than those Licentiates. But unless this proposition is maintained, the advantage which the public derive from the power given by the bill to the Apothecaries over quacks, cannot be stated as a reason for giving them a similar power over regularly-educated physicians and surgeons. It were surely easy to provide, if much real difficulty be felt in this matter, that all medical Graduates of Universities, or Licentiates of the recognized schools of surgery, who propose to dispense as well as prescribe medicines in England and Wales, should be required to register their names and shew their diplomas, or lodge certificates of these, at the Apothecaries' Hall, without imposing on them the necessity either of the examination before the Apothecaries or of the five years' apprenticeship to members of that body.

It is true that in this, as in most other cases of alleged grievance, the remonstrance comes from interested parties, and ought to be the more carefully scrutinized on that account; but it is only, in so far as we can make out a case of injury, first, to a large body of well-educated men, and then to the public at large, as well as to ourselves,

that we petition for the interference of the legislature; and the advantages of ample education, and of free competition, are now so generally appreciated, that I apprehend the *onus probandi* must rest heavily on those who stand up for an enactment which debars the regularly-educated Graduates and Licentiates of the medical schools of Edinburgh and Glasgow from a line of practice in England and Wales, which they actually adopt in Scotland, and in other parts of the world, whenever it suits their convenience; which they did adopt, prior to 1815, in England also; by pursuing which, many of them, in all parts of the world, have raised themselves to the first eminence in their profession; and from their pursuing which, no injury to the public, at any time or place, is even alleged to have resulted.

With regard to what has been said of Graduates of this University having been found deficient in practical knowledge of pharmacy, when examined in London,—without attaching any weight to what has been urged on us by several Graduates, viz. that such examinations have been unfairly conducted, and without even laying any stress on the fact just stated, that the competency of the Edinburgh Graduates and Licentiates to dispense medicines is proved by the experience of their habitual practice in Scotland and in the Colonies, and in England prior to 1815,—I would merely beg you to observe, that this University have expressed their willingness to concur in an enactment imposing on all their Graduates who may propose to act as general practitioners, and who may not have been habituated to the dispensing of medicines by apprenticeship, the obligation of serving for six months in a laboratory, to acquire practical acquaintance with this part of their duty; and from this provision, coupled with the knowledge of chemistry, botany, and *materia medica*, which is required of them by regulations and enforced by examination, it appears to me that the public will have as ample security on this point as can possibly be desired.—I have the honour to be,

Sir,

Your very obedient servant,
W. P. ALISON, M.D.

Professor of the Institutes of Medicine.

DEFENCE OF THE APOTHECARIES' COMPANY;

IN REPLY TO MAXILLA INFERIOR.

To the Editor of the Medical Gazette.

SIR,

As you have inserted in your columns the lucubrations of Maxilla Inferior, I hope you will permit me, through the same channel, to reply to the observations of that writer contained in your last number.

Maxilla Inferior asks, what it is which Scotch professors, pupils, and graduates *in esse* and *in posse*, have been petitioning the legislature for? Surely this sagacious writer might easily have surmised why there has been such an unanimity of feeling amongst those various ranks in Aberdeen, Glasgow, and Edinburgh. From the almost exclusive advantages to the Scotch schools, contained in the Bill now before Parliament for the amendment of the Apothecaries' Act, we may fairly suppose the cause to be, that the above universities have already overstocked with their graduates every place open to them by the existing law. The whole of Scotland swarms with them—our army and navy lists can boast a goodly show of them, and the physicians throughout England, the metropolis excepted, are almost entirely graduates of the Scotch schools. It therefore became necessary that some new plan should be devised, to provide for—some new outlet be found, to let off—this superfluous abundance of medical practitioners; and to Scotch second-sight the Goshen of England presented itself open to the brilliant experiment of physician-apothecaries, and surgeon-apothecaries, having received their elementary education behind a druggist's counter. Should not the scheme succeed, professors, from the glut in the market, must cease to have pupils, at least in the present lucrative numbers, and pupils and graduates *in esse* and *in posse*, must run the risk of feeding upon their own medical attainments. Besides, there is an additional advantage in favour of the Scotch universities, should the present Apothecaries' Bill pass into a law; for as the fees in the Scotch universities for lectures and diplomas are lower, and the cost of living less, in the northern

cities than in London, and as the diplomas will enable their possessors to practise as apothecaries in England and Wales, so it follows, of course, the lecture-rooms and hospitals of London will be deserted by the English pupils for those of Aberdeen, Glasgow, and Edinburgh. Why need we seek for other motives than these to account for the anxiety of the Scotch professors that the present Bill should pass?

I beg now to reply to Maxilla Inferior's law opinion as to what the Scotch graduates do *now* possess. If Maxilla Inferior be correct, that a Scotch surgeon can now act as a general practitioner in London, by the easy subterfuge of having his prescriptions made up at a chemist's, why are the Scotch professors, pupils, and graduates, so anxious for the enactment of the Bill? But I believe he is aware that such right does not exist, and cannot be exercised except by stealthy management. For proof of this I would refer him to the issue of the trial of the College of Physicians *versus* Dr. Harrison, in which a verdict was given in the Doctor's favour, only on the plea advanced, that he had prescribed as a surgeon in a surgical complaint. Alexander Mackintosh, surgeon, with an Edinburgh diploma, in the hypothetical case of Maxilla Inferior, would be in a similar predicament, and could only escape the College in a similar way. But even this would not avail him; for if Mr. Willecock be right in his law, who states, at page 64 of his work "On the Laws relating to the Medical Profession," that none can practise surgery in London until examined and admitted by the College of Surgeons, then the supposed Mr. Alexander Mackintosh would be amenable to the said College for presuming to practise without their license.

Maxilla Inferior acknowledges that the present Apothecaries' Act has effected much good, and merits the encomiums which the profession generally has bestowed upon it. Why then virtually annihilate it? The Act has done much good, by enforcing a steady and efficient mode of medical education, in wisely insisting upon a five years' apprenticeship to a regular practitioner, during which a young man daily compounds, dispenses, and watches the operation of various medicines, and obtains by the continued instruction of his master a general knowledge of diseases,

rendered a scientific one by subsequently attending lectures upon the principles and practice of medicine. That the Apothecaries' Company took a sound view of the matter, the result has proved; and the practitioners practising under their license may without risk court inquiry as to their respectability, professionally considered. And I think, before any alteration be made in the law, for the benefit of the Scotch practitioners at the expense of the English, such inquiry should be established. It ought to be ascertained whether the English practitioners are, or are not, worthy of the public confidence; and it ought to be clearly demonstrated that the public would benefit by the change. The reverse of the latter point I honestly believe would prove to be the case. For, instead of the valuable instructions of a five years' apprenticeship, the preparatory education of a few months employed in the dispensing of medicine in a druggist's shop, is one of the qualifications substituted. Nor is the subsequent requirement of medical lectures and examination any assurance that the public would not by these means have to suffer from unskilful practitioners; as we all well know that an examination may be passed through brilliantly by dint of grinding, without the examined possessing any substantial practical knowledge. Again, by what means are prosecutions protective of the public against quacks to be carried on? Is it to be presumed that the Scotch universities will extend their care to England and Wales, and spend the money which this Bill, if enacted, will pour into their coffers, to protect the English public?—Can any one believe that such will be the case? Can the Apothecaries' Company do so when their funds are dried up? for let London especially, and England generally, consider, that if this Bill should pass, the medical schools of our metropolis will die away—the hospitals will be deserted, not only by the pupils, but probably by the present talented professional officers, who will lose the remuneration for their services which pupilage affords; and the London College of Surgeons and Company of Apothecaries, which have each so much raised the standard of professional information, will cease to exist for any useful purpose.

Permit me next to notice Maxilla Inferior's objections to the working of the Apothecaries' Act as to the Latin examina-

tions, which he suggests should take place at the end of the apprenticeship; and why? in order that the pupil may not be troubled to occupy himself with "*hic, hæc, hoc*," during his courses of lectures. But surely a pupil, knowing the nature of his final examination, will not defer his classical studies to this period; and it happens that the time when it is necessary to ascertain whether he be qualified in this particular, is when Latin reading is likely to be useful to him—at the time when he is to commence practice for himself. I can see no reasonable ground of objection in this particular, unless it be, that the Company, who voluntarily have made respectable classical attainment one rule of fitness for the profession, are not to be trusted to continue it, without adding a clause in the Act to *force* them to do so. Let any reasonable man look at the requirements of the Apothecaries' Company for examination, as set down at page 15 of volume vii. Medical Gazette, and say whether they are not ample to secure sound medical and sufficient classical knowledge. Then why change? Maxilla Inferior's reason, that "a good house admits of improvement, and in the lapse of years requires repair," is not satisfactory. Let him remember the old adage, "*let well alone*." He who is fastidious enough to be always altering a good house often spoils it; nor are there many good houses of eighteen years old, the age of that excellent structure the Apothecaries' Act, which require repair as extensive as that proposed for the Apothecaries' Act in the present Bill,—which amounts to pulling the house down to the basement story. That I may not appear to be praising myself in the commendations I have bestowed on the members of the Apothecaries' Company, I beg to say that I am not a licentiate of that body, although

A COUNTRY MEDICAL PRACTITIONER.

CLAIMS OF EDINBURGH SURGEONS.

To the Editor of the Medical Gazette.

June 8, 1833.

SIR,

NOTWITHSTANDING that you seem so much in arrear with your correspondents, I must trouble you with one remark,

in correction of a statement which appears in your leading article for this day. It is there argued against the claims of the Edinburgh College of Surgeons, that the diplomatist of that corporation is certified to be only "*ad artem CHIRURGICAM exercendam quam maxime paratus*." Now, I transcribe the following words from an Edinburgh diploma, which is lying open before me:—"Hiscæ literis testatum volumus virum ingeniosum—examini sese subjecisse, et quæstionibus de rebus anatomicis, chirurgicis, et PHARMACEUTICIS ei propositis, responsa satis apta et docta publice reddidisse." Surely, sir, these expressions, coupled with the well-known regulation demanding that candidates for the Edinburgh diploma shall produce certificates of attendance on full courses of theory and practice of medicine, will satisfy any calm and candid reasoner that the Edinburgh College has framed its laws, and not inefficiently, with a view to the providing of Scotland, not merely with *surgeons*, but with *thorough-bred general practitioners*. This fact ought not to be lost sight of for a moment, while the question as to the expediency of a free medical practice between North and South Britain is being agitated. The exclusion of the London College of Surgeons cannot be wondered at, while that body confines its examinations to anatomy and surgery.—I remain, sir,

Your obedient servant,

Φ.

[It appears by our correspondent's own shewing that the difference between the Edinburgh and London College of Surgeons is, that the former examines in pharmacy, and the latter does not;—and yet he regards this as a sufficient reason for admitting the members of the one, and rejecting those of the other. Pharmacy is but one branch, and though a necessary, yet a very inferior grade of medical science. Every chemist and druggist knows more *de rebus pharmaceuticis* than most physicians, surgeons, or general practitioners; and if a knowledge of pharmacy is evidence of a man being fit to practise medicine, then, of course, chemists and druggists ought to be allowed to do so. We repeat, the members of the Edinburgh College of Surgeons cannot be admitted as general practitioners in England, unless the privilege be extended to those of the London College.—ED. GAZ.]

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégier.”—D'ALEMBERT.

Sketches from the Case-book, to illustrate the Influence of the Mind on the Body; with the Treatment of some of the more important Brain and Nervous Disturbances which arise from this influence. By R. FLETCHER, Esq., Surgeon to the Gloucester General Hospital, &c.

THERE is much in the style as well as the subject of this volume which makes it a novelty among medical publications. That it is a medical work we would fain believe, from the mention of “case-book,” and “treatment,” and “brain and nervous disturbances,” in the title-page; but truth to say, after reading it through, we must pronounce it to be a production almost *sui generis*: and as regards medicine—“throw physic to the dogs,” would seem to be the author's motto. When Macbeth says to his physician, “Canst thou not minister to a mind diseased—Pluck from the memory a rooted sorrow?” &c., the physician doubtingly replies, “Therein the patient must minister to himself.” Now Mr. Fletcher's object is to shew *whereby* the patient may so minister; and, in brief, his method is—to engage the patient to take to composition. Is any one afflicted with real or imaginary woes—with blasted hopes—disappointed love—jealousy—or any other distracting passion, let him take up his pen and write: *compose*, and be composed.

What claim Mr. Fletcher may have to the invention of this *medicina animæ* we shall not stay to decide; we recollect, however, having met somewhere in the works of the poets certain laments, and monodies, and stanzas, on the deaths of beloved wives, and mistresses, and children; but Mr. F. certainly seems entitled to the merit of recommending “composition” with the greatest latitude that we have hitherto observed. *Nolentes volentes*, his patients with troubled minds, *indocti doctique*, must sit down to their writing-tables; or, if they labour under a want of sufficient composure, or a lack of ideas, ramble into the open air,—always with their pencils and note-books in their hands. What *kind* of composition he would ad-

vise, the author does not exactly say; poetry perhaps, or poetical prose; we should presume the latter, judging from the style of the volume before us. But, to be sure, it is no affair of ours what the poor sufferers write: let their publishers look to that—the editors of magazines and newspapers more especially—for theirs is the province threatened with invasion. Medicine, we hope, is safe.

We proceed to lay an extract or two before the reader, by which he will be enabled to see how perfectly Mr. Fletcher contrives to blend precept and example together. Some of the luxuries of the following passage we are obliged to omit, in our economy of space.

“Reader, if thou art one of those numerous children of misfortune, a part of that dark mass of misery, which overshadows, and attires in mourning the fair face of the earth, rise early; for bed, in thy waking hour, will be the *cradle of thy woe*, and not the place for thy repose.

“There may come periods when the memory of thy misfortunes, or thy broken and blighted affections, of their lost and once precious endearments, will *find thee out*,—probably on thy pillow. Reader, lose no time, if thou valuest health, and above all, thy reason; rise instantly, and to work, or take thy sketch and note-books, and seek at day-break that cheering light which awakens hope, soothes to peace, and heals, at least for a while, the broken heart.

“Go, seek some elevated spot, endeared by loved and early recollections, now indeed fading away, and there *await the glory which is coming*, and with it a certain consolation for thy bitterest moments;—*there* thy frame, though withered by the blasts of a life of misery, shall be refreshed, and thy soul reanimated with hope, long since a stranger to thy bosom. Turn thine eye eastward, and watch the first approach of the beautiful morning light, as it breaks over thy native hills, and trembles on their tops; observe the light clouds as they skim along the grey vault of heaven, and feel then the sublime and beautiful notions thus yielded, of immense distance, of worlds beyond, and of a mighty power!

“These *light and feathery messengers*, borne by the gentle and almost noiseless

breeze, scarce trembling among the trees, precede and announce the silent, immediate, and magnificent approach of the orb of day. Nearest the dawn, heavy masses of grey clouds are seen to blush deep red, and soon the whole firmament glows with a rich golden light, which touching with brilliant lustre the mountain's brow, leaves its sides and the valley as yet clothed in deep and misty shadow. Observe, now, *the morning breeze, and these splendid rays, roll away the wreathy vapours from the tall elms, touch with diamond brightness the delicious green of their elegant tops, reeking with dewy freshness.* See, in another direction, the increasing heat and breeze sweep away the fog, and then slowly reveal the calm unpretending beauties of the distant landscape, the *bleating lamb, or lowing cattle, marking the green banks of a clear stream winding through the plain, and bearing on its quiet bosom a little bark!* Reader, *its flitting sail, sometimes here, sometimes there, and now lost for ever, is an emblem of life;* and should remind thee of the approaching, and, perhaps, sudden termination, of thy earthly woes!"

The depth, originality, and pathos, of this concluding apostrophe, must strike every reader.

But we must give one of the "Sketches." The following is the first in the book, and a magnificent one it must be allowed to be, to begin with. How unlike the vulgar form commonly observed in medical cases!—

"A guest, in a noble castle, in whose halls reigns [reign] magnificence and princely hospitality, was intently observing, on a fine October morning, the various preparations for a happy day. *Examples of the best and most generous blood in the kingdom were keenly engaged in various objects of interest; some in lolling over a magnificent breakfast, and speaking rapturously of no common deeds soon to come. Others, preparing their guns, or strolling about the domain, were gazing at the fine effect of the morning sun, as its rays glistened in summer warmth among the polished ivy, which embraced the ancient turrets of the castle.* These, by their pensive positions, were probably gathering up in memory the melancholy but precious associations with days that were gone, and drawing painful conclusions on the uncertainty of human life, and

perishable character of all earthly grandeur! But this almost royal abode is no place for melancholy, or grave reflections.

"The eye quitted the ancient pile and its *reminiscences*, and turned towards a more cheering view;—*the glorious luminary of day, with the fresh gale of autumn, slowly dispersing the mist from the bold and proud forms of the oak, and groups of the tall and aged fir, as they were spread in masses of majestic grandeur over the wide bosom of the park.* Soon the breeze and the sun together, rolled away the morning fog from another interesting object—the unrivalled and far-famed *kenel* in the distance. Taste varies. A stroller, with folded arms, leaning on the parapet, might now be seen turning his ear to *this building.* He is *silently* listening to the *cheering* note of the *eager* fox-hound, as it is borne on the gale, and soon will be be of that *happy* number, who in the rear of these *gallant* dogs, shall give the last *brilliant* touches of scarlet to the *rich and glowing* tones of the *autumnal* landscape.

"The guest crossed the castle court and entered the park. The morning breeze blew kindly in his face, and freshened with temporary vigour a languid and failing frame. Hitherto, even unto him, all was brilliant and full of hope; and happiness, for a day, was apparently within his reach. *But what can ensure it for a moment in this world?* A single thought stole cruelly into memory, and poisoned the cup already at the lip;—in an instant, pleasure and hope vanished together,—and not a vestige of the boundless beauties around him remained. *The double shot 'mark.'*" [?] the last whirl and note of the most beautiful tenant of the English forest, were unheard, or if heard, unnoticed; the cry of the fox-hound was mournful; a dark and gloomy mantle overspread the once bright landscape.

"*'What is the matter,' said a friend, 'are you ill? How changed you look.'* The reply was short, for the heart of the sufferer was full. The friend passed on—the guest felt he was ill—that the change was great; and the whole was but a moment's work of the mind of man.

"The thought which worked this mischief was a frequent visitor to the brain of the individual in question. But of late, unsparing and repeated blows had

made it sore and rebellious. Pains in the head succeeded to the last visit narrated above, and it was years before the derangements of the health, the effects of these mental irritations, were even partially removed.

"It was not long after the park scene already narrated, that the same individual, who having as usual dwelt upon his sorrows in bed, rushed from it in such a pitiable state of irritability from long suffering, disgust, mental anguish, and bodily pain, that he passed down stairs, sensitively fearing to encounter an unkind eye, or the sound of an unfriendly foot-fall, exquisitely open to every trifling injury, and yet receiving mental wounds from all quarters. [Qu. *Priscian*.] The breakfast-room, filled with the most precious remains of art, now no longer seen, to him had all the sad and gloomy air of *a sepulture*; the singing of the urn, so cheering to the happy, was the hissing of the snake; the food had the bitterness of gall, and it was certainly a mere *casualty* whether he employed the knife intended to cut it, *in more ways than one*. But a soft and gentle voice struck his ear. On turning, he beheld his beloved daughter. 'Papa, I have been copying this morning for you, does it please you?' offering the fruit of her morning's industry, with a deep tone of tenderness and look of affection! *Man is a strange animal!* In an instant the fire burnt brighter, the sun shone with unusual splendour through the ancient stained glass, the tea-kettle [urn?] yielded its cheering song, the appetite returned, and for a time at least hope occupied the dwelling-place of misery!"

It will be seen from the foregoing specimens that Mr. Fletcher's volume is one of no common description. Indeed we know not when we perused a work that excited in us such a singular degree of interest. It is truly a phenomenon in medical literature: but as it is not encumbered with much medical knowledge, or at least medical technicalities—if we except some curious phrases, which we hesitate to call medical, such as "mental indigestion," "mental hypochondriasis," &c.—it is very well calculated to have an extensive circulation among the author's patients, and to carry his fame far beyond the narrow limits of the medical world.

CICERO.

AMENDED APOTHECARIES' BILL.

THE Bill, which at present occupies so large a share of attention in the medical world, has been committed, and is expected to be discussed on Monday next. It was stated by Mr. Lamb (on the second reading) that he had communicated with various public bodies interested in the question, and that several amendments had been agreed upon.

We last week expressed our belief that this would be the case, and we hinted at the nature of the changes which were likely to be made in the Act. We have ascertained what these are to be—at least what the parties here have been led to suppose would be conceded to them, and introduced as clauses, prior to the Bill being laid before the Committee of the House. But there has been so much changing and hesitation, and, apparently, such an entire ignorance of the bearings of the question, where they ought to have been most thoroughly understood—so much disposition manifested to legislate first and inquire afterwards—so much intriguing and private influence, and so great an exertion made by the agents of the Scotch Colleges to have their Bill carried through in all its integrity—that we shall not feel satisfied that there is no jugglery intended until the Bill be actually carried, or at least till we shall have seen it printed with its promised improvements.

The great bone of contention regards the Scotch diplomatists in surgery. The English College does not possess, and does not aspire to, the privilege of granting licenses to general practice: the parties know, and feel, that the moment they did so, they would

become a College of Apothecaries; and though there be three or four in the Council who openly profess their preference of a measure which would necessarily lead to this result, yet the majority (and it is a large one) desire to retain the higher ground which they at present occupy. Such being the case, the question as regards the proposed Act is, whether a privilege is to be forced upon the gentlemen of Lincoln's-Inn Fields which they do not covet; or a jurisdiction to be given to the Edinburgh and Glasgow surgeons over the practice in England, in which the London College of Surgeons does not participate? The mode of obviating this palpable inconsistency we believe will be, a provision that none of the Colleges of Surgeons shall have the power to grant licenses to practise medicine, but that the holders of their diplomas shall have greater facilities than heretofore of obtaining such license. For example, that they shall be entitled to examination at Apothecaries' Hall, with a view to becoming general practitioners, on the strength of their diploma, and that such examination shall not be extended to the branches on which the surgeons found *their* test of qualification, viz. anatomy, physiology, and surgery. It is understood that certain modifications will be made regarding some of the branches of education to be pursued by the candidates for surgical diplomas, particularly with reference to attendance on *medical* in addition to surgical practice, and to the acquirement of a familiarity with pharmaceutical manipulations in the laboratory of an apothecary. This arrangement it behoves the London College of Surgeons to carry into effect, not only on the broad principle of its utility, but as a mere matter of policy, in order that their diplomatists may be placed on the same level with regard to professional acquirements as their rivals of Edinburgh.

With regard to the Scotch graduates in medicine, they are to be entitled to their license as apothecaries on registering their degrees at the Hall in London; it being understood, however, that a knowledge of practical pharmacy has been previously attained in the manner above mentioned.

Should these arrangements be carried into effect, the most objectionable parts of the Apothecaries' Act will have been got rid of, and both they, on the one hand, and the Scotch Colleges on the other, will have obtained all that they are entitled to, or can reasonably demand. The former, we have reason to believe, will be perfectly satisfied; the latter, we presume, will not.

But the government may rest assured that if more be conceded than we have above described, the discontent which will be excited throughout England—in the large, respectable, and influential body of men who constitute the present race of general practitioners—will be such as there may be reason to regret having excited. Though lulled for a time into a false security, partly by the persuasion that nothing so unjust as the enactments of the Scotch Bill would be granted, and partly by the treacherous deceptions of the pretended guardian of their interests, yet are they at length rousing themselves from their apathy, and petitions now, at the eleventh hour, are beginning to be forwarded from most of the provincial towns. Should the Bill not prove to have been modified to the full extent we have mentioned, we would recommend that no time be lost in transmitting petitions to the Upper House: it will then be too late for them to avail with the Commons. Indeed, we believe but little effort would be required to have the Bill, as originally printed, thrown out by the Peers, should it ever arrive there. If we might venture to advise, with respect to such petitions, we would urge

the propriety, as well as policy, of avoiding recrimination; and we do this the rather, from observing that the petition of the Committee of the "Associated General Practitioners," which we inserted last week, is unjustly and splenetically severe in reference to the system of medical education in Scotland.

We have given a variety of documents and correspondence, in our present number, on the subject under discussion; but of these, the only one to which we deem it necessary to refer particularly is the letter of the learned Professor of the Institutes of Medicine in Edinburgh. Dr. Alison does, and therefore others may, mistake our opinions on several essential points.

It does not follow, because we have lent our feeble aid in support of the Society of Apothecaries, against a measure which would be so injurious to the interests of the general practitioners in England as this Scotch Bill — we say it by no means follows, because we resist this aggression, that we therefore approve of all the details of the Apothecaries' Act. Far otherwise: we have many times, and in strong language, protested against various parts of it—particularly the apprenticeship; while, with respect to the gentlemen themselves, at Blackfriars, we have taken the liberty of objecting to their proceedings, as occasionally too busy and meddling. We think particularly, that it was most injudicious ever to subject the Scotch Graduates in medicine to examination on their general acquirements in medicine. The consequences of rejecting any of the Edinburgh physicians were so obvious, that it is astonishing the Society of Apothecaries did not avoid them. Had they been the most liberal Examiners, and the most just and upright judges that ever existed, they would not have escaped the imputation of unfairness and partiality. But on

the other hand, as regards the University of Edinburgh, we have said, and we repeat, that it is not calculated to raise them in the estimation of the public, that they should be so eager to procure the recognition of their medical Graduates as English apothecaries, without examination, while they tamely submit to their being compelled to pass through a second ordeal before their admission into the body of English *physicians*, and then only to obtain a license to practise and be recognized as members of an inferior order.

—

IRISH GRAND JURY BILL.

THIS crooked piece of legislation, with its obnoxious clause, affecting the interests of so large a body of medical practitioners in Ireland, after passing successively through the hands of Mr. Stanley, Sir John Hobhouse, and Lord Duncannon, into those of Mr. Littleton, has been at length put aside till next session. The *liberal* party in York-Street will thus have leisure to concoct new schemes, and to devise fresh instructions for their emissaries—who, by the way, have a very pleasant job of it every summer. We trust that the interval which is now gained will not be foolishly squandered away by those who, if the clause alluded to be carried in its present form, will, we foresee, be loud in their clamours against alleged injustice hereafter.

MEMORIAL

For the Senatus Academicus of the University of Edinburgh, respectfully submitted to his Majesty's Principal Secretary of State for the Home Department.

BEFORE the year 1815, when the Act to regulate the practice of Apothecaries in England and Wales was passed, graduates of the University of Edinburgh were at liberty to settle in any part of England and Wales as general practitioners, and to dispense medicines to their patients. The object of the Act of 55 Geo. III., against which the present remonstrance is di-

rected, was to secure the public against medicines being prescribed and dispensed by men *less* educated than the licentiates of the Company of Apothecaries in London; but its practical effect, in so far as gentlemen possessing the degree of M.D. from this University are affected by it, is to prevent men *better* educated than the great majority of those licentiates from engaging in such practice.

It is well known that the distinctions of physician, surgeon, and apothecary, are strictly observed only in large towns, and by a part of the practitioners in these; and that the great majority of those to whom the health of the community must be intrusted, in all parts of this country, act during the greater period of their lives as general practitioners, dispensing as well as prescribing medicines.

It is humbly submitted, that medical men should be left at liberty to avail themselves of their talents and acquirements in the exercise of their profession, in any way which they may find most to their own advantage, and to accommodate themselves to the habits, wishes, and even prejudices, of the people among whom they reside, provided only that they possess certificates of having duly qualified themselves, by education, for whatever duties they undertake. The proper object of legislation, in regard to the profession, is conceived to be—not to lay down for any class of medical men the mode of practice which they shall exclusively adopt, but only to secure, that they shall undertake none without the requisite education and preparation.

But if any preference is shewn by legal provisions to one class of practitioners over another, it should be to those whose education has been the most ample and scientific. If those who have taken the degree of M.D. after a full course of study at universities and hospitals, and strict examinations by the professors of the different branches of medical science, are willing to act as general practitioners, it is for the interest of the public that they should be encouraged to do so, rather than those who have gone through a shorter course of study, and had less opportunities of acquiring information as to the most difficult part of their profession, viz. the discrimination and proper treatment of disease, which is certainly a matter of much greater difficulty than the compounding and dispensing of medicines—particularly in this country, where the general practitioner is always supplied by the professed chemist or druggist with all medicines that are of difficult preparation.

It will not be denied that, on these grounds, the graduates of this University have higher claims to public confidence and support, as medical practitioners, than

the licentiates of the Company of Apothecaries; but the effect of the Apothecaries' Act is to prohibit any of those graduates from acting as general practitioners in England or Wales, unless, in addition to their studies at universities and hospitals, they have served five years' apprenticeships to members of the Apothecaries' Company; while those who have this last qualification are allowed to act as general practitioners, under a license from that Company, after a course of study of half the duration, and of a much more superficial nature.

The practical effect of this enactment is, therefore, to limit the number of fully educated practitioners in England and Wales, and to throw the charge of the health of the community into the hands of men of a lower grade of education and acquirements than those possess who might otherwise have undertaken that duty.

That the number of medical graduates (*i. e.* of fully educated practitioners) who are engaged in medical practice in England and Wales, is much less in proportion to the population than in Scotland or Ireland, or in France or Germany, is easily demonstrated by reference to the number of graduates of these countries who have taken their degrees in any of the great schools in a given time.

In this University during the last eight years, the number of gentlemen from England and Wales who have taken the degree of M.D. is 281, which is almost exactly the same as the number of Scotch graduates during the same time (279); and is considerably less than the number of Irish graduates in the same eight years, which is 310. When it is remembered that the annual number of medical graduations at Oxford and Cambridge is always small, and that the number at Dublin and Glasgow is very considerable, this single fact unequivocally demonstrates that the encouragement given in England to fully educated men, as compared with that given either in Scotland or Ireland, is by no means such as ought to be expected from the superior population and wealth of the former country.

It is true, that the knowledge of the preparation and compounding of medicines, although of less difficult acquisition than that of the nature and treatment of diseases, is yet of such importance to the community, that ample security is required of its being possessed by all general practitioners; but many of the medical graduates of this University have received ample practical instruction of this kind, by apprenticeship to Fellows of the different Colleges of Surgeons, or by apprenticeship to hospitals, although they have not been apprenticed to members of the Company of Apothecaries. For those who

have not been apprentices, the memorialists confidently assert, that in addition to the attendance on full courses of lectures on chemistry, botany, and *materia medica*, as they are here taught, and the examinations by the professors of these sciences, which all Edinburgh graduates must undergo, six months of attendance at the shop of an apothecary, or in the laboratory of an hospital or dispensary, is amply sufficient to qualify them for dispensing medicines to their own patients; and certificates of such attendance may easily be required; but it is respectfully submitted, that to require from them the certificate of the long course of *apprenticeship* to members of the Company of Apothecaries, in addition to their course of study at universities and hospitals, can have no other effect on the interest of the public, than the injurious one above stated.

In confirmation of the view of this subject which is here taken, the memorialists beg leave to subjoin an extract from the report of the Royal Commissioners appointed some years ago to visit the Scottish universities:—

“In reference to the subject of the system of instruction in the science of medicine afforded in the Scotch universities, our attention has been directed to a matter of very great importance to the interests of these universities, by the earnest and pointed representations of a great number of the witnesses examined: we allude to the enactments contained in a statute passed in the year 1815, called the Apothecaries’ Act. By that statute all persons are prevented from practising as apothecaries in England and Wales unless they are licensed by the Apothecaries’ Company in London. Although the Act apparently only confers on the Company the privilege of licensing apothecaries, it has been stated to us, upon unquestionable authority, that under this denomination are included nine-tenths of the practitioners in England. It is only in large towns, and probably rarely even in them, that the different departments of physician, surgeon, and apothecary, are kept separate: generally, throughout the country, it is necessary for every practitioner to dispense drugs. Hence the statute really confers upon the Apothecaries’ Company the monopoly of licensing all the general practitioners in England and Wales.

“The result of the operation of this statute is to exclude the whole graduates of the Scotch universities from practising in England, unless they are licensed by the Apothecaries’ Company, to which they are not admitted as candidates until after having served a five years’ apprenticeship to one of their licentiates. It humbly appears to us that while this regulation is

most unjust in its consequences to the graduates of the Scotch universities, and inconsistent with the privileges which ought to belong to the universities of one part of the United Kingdom, it is at the same time most injurious to the interests of the community, by tending to exclude those who are best educated by preparatory and professional knowledge for the medical profession from becoming general practitioners in England. It would be absurd to compare for a moment the education prescribed for the medical graduates of the Universities of Edinburgh and Glasgow, with the requisites exacted from the persons licensed by the Apothecaries’ Company. The direct effect of the enactment is to vest the monopoly of practice in a class of persons of very inferior education.”

PETITIONS AGAINST THE SCOTCH APOTHECARIES’ BILL.

THE parties whose interests are immediately threatened in the projected change of the Act of 1815, are, we perceive, on the alert at last, throughout the country. Various petitions have been forwarded to us, but it is not possible to find room for more than some of their leading points. One

From WAKEFIELD,

Sheweth, That the petitioners view with apprehension the measure now before parliament, because, 1. “The Company of Apothecaries is the only jurisdiction in the medical profession which can exercise an authority for the protection of its members and licentiates throughout the whole of England and Wales; an authority which is especially necessary for the prevention of quackery and the guardianship of the public health.

“And, 2dly, because the said Society have made great and laudable exertions since the passing of the Act of 1815, to improve the general character of the profession, by demanding extensive qualifications from the candidates for their license; and have also kept pace with the gradual advancement of professional knowledge, by increasing the severity of their examinations, so that none but such as are well qualified to act as general practitioners can be admitted as licentiates of the Society.”

Whence they “entreat that such a protection and guarantee, both to the public and the profession, may not be interfered with, or altered, without substituting at least an equally efficient one in its place.”

The petitioners deprecate the idea of a

monopoly in any medical corporation, but they pray that one standard should be adopted as the minimum of attainment in a candidate for the same degree of professional rank, in all the halls and colleges of medicine, surgery, and pharmacy, in the United Kingdom. "They would heartily concur in any measure which, with this provision, was intended to throw open the rights and privileges now enjoyed by the Society of Apothecaries to the members and licentiates of all such legally-constituted colleges and halls, along with further protective enactments, if the legislature should deem them adviseable; but they entreat the members of your Honourable House, before they pass so important a measure as that they have alluded to, to inquire strictly whether the qualifications of many of those individuals whom that Act would admit as general practitioners in England, are necessarily equivalent to the standard required by the Apothecaries' Company of London."

Signed by Caleb Crowther, M.D.; Wm. Thomas, M.D.; T. G. Wright, M.D.; Benjamin Walker, Surgeon, and sixteen others.

From BRADFORD,

A numerous signed petition sets forth, that the Bill now before the House is viewed with disapprobation and anxiety; inasmuch as it tends to throw down those excellent barriers which have for many years opposed the admission of unqualified persons to the general practice of medicine in this country, and conceiving it to be of the highest importance to the public welfare that those regulations should continue in force which have been found so essentially to raise and improve the character and consequent utility of the profession, and to secure unto the public a supply of practitioners properly competent to the discharge of their duties.

After a high eulogium on the competency and impartiality of the Court of Examiners, the petitioners proceed to state their conviction "that the chief glory of the medical profession must result from the personal character and professional competency of its members; and they deprecate the changes now proposed, as being calculated, in a great degree, to subvert these important objects, by throwing open the whole kingdom to the fearful consequences of imperfectly qualified individuals undertaking the important duties of the medical profession."

In conclusion, the petitioners "beseech the Honourable House either to confirm or continue the present professional regulations, as existing in and for this kingdom, or so to modify the whole system as that no one body of the profession shall

enjoy any exclusive privileges to the injury of any other."

A petition, signed by thirty-four medical practitioners, which has been sent us

From HULL,

"Sheweth, That your petitioners have learnt with deep regret, that a Bill has lately been brought before your Honourable House to amend an Act of the 55th year of his Majesty King George III., for better regulating the practice of Apothecaries throughout England and Wales, which, if passed into a law, will so far modify as nearly to amount to an annihilation of the Society of Apothecaries; whose zealous, honest, and judicious efforts, have led to that superior and practical system of education which now exists in the London and provincial schools, and which merits the warmest commendation of the public in general.

"That the persons who claim the privilege of practising as general practitioners by the amended Bill, are not, in the opinion of your petitioners, entitled to it; inasmuch as the advantages afforded to the students in London, by the practice of its numerous hospitals, which contain 2310 beds, are far superior to those which can be obtained in Edinburgh, where there is only one hospital, containing 250 beds.

"That, in conclusion, your petitioners beg to state, that if this Bill be passed into a law, the controlling power at present exercised by the Society of Apothecaries, with so much benefit to the community at large, will be destroyed, the standard of medical education lowered, and great difficulties will arise in the prosecution of persons not legally qualified to practise."

A resolution also unanimously adopted by a large meeting of general practitioners, has been sent us

From BIRMINGHAM,

Setting forth, "That the governing body of the Apothecaries' Company are entitled to the gratitude and confidence of the general practitioners of medicine in England and Wales, for the zeal, intelligence, and success, with which they have laboured to promote and exalt the respectability of the medical profession, by progressively raising the standard of education *pari passu* with the advancing state of general knowledge; by exercising judiciously the power entrusted to them by the legislature, for the prevention of incompetent persons practising in that department of medicine over which the Apothecaries' Company preside; by vigilant attention to the interests and character of the medical profession, as evinced, not only in the effects

before-mentioned, but also in resisting innovations which tend in any degree to the injury of the medical practitioners in England and Wales." They then proceed to state their reliance on the wisdom of the Company, to use all just means of protecting the licentiates: and with regard to the contemplated change in the apprenticeship system, while they admit that the latter is "objectionable, in so far as it assimilates to a certain extent medical pupillage to menial servitude," they deprecate any alteration, without the most serious and deliberate regard to what is requisite for maintaining the respectability and the usefulness of the medical profession.

(Signed) W. SANDS COX, Chairman,
On behalf of the Meeting.

EXTRACTS FROM JOURNALS, *Foreign and Domestic.*

IS THERE ARSENIC IN THE MATERIAL OF TEST TUBES?

AN inquiry of considerable importance in legal medicine has been recently made by a commission of the French Academy. The question was put to that learned body by the Minister of Justice (in consequence of the alleged detection of arsenic in a body seven years buried*), whether the metal arsenic, said to have been reduced, did not really come from the oxide contained in the glass of the test-tube? The conclusion arrived at by the reporters, is, that there is no arsenic in the common white tube-glass, and that even where a small quantity has been added in the fusion, no traces of it can be detected in the usual process of experimenting.

CONSTITUENTS OF OPIUM.

M. Pelletier, in a memoir published not long ago, in the *Annales de Chimie*, thus enumerates the ascertained principles of opium:—narcotine, morphia, meconic acid, meconine, narcine, caoutchouc, gum, bassorine, lignia, resin, brown acid and extractive matter, fixed oil, and a volatile but non-oleaginous substance rising in distillation with water. M. Bebert (*Journal de Pharmacie*) adds another—viz. a bitter crystallizable substance forming salts with acids, especially the acetic acid, and to which no name has yet been given. M. Robiquet, also, has further obtained a new alkali from opium—viz. *paterin*; a notice of which is given in the *Journ. de Pharm.* for November 1832. Unlike the other vegeto-alkalies, it is soluble in water, saturates acids, is insoluble in potassa, and contains much azote; it is very poisonous, and has a special action on the spinal cord.

* See Med. Gaz. vol. v. p. 411.

BIRMINGHAM SCHOOL OF MEDICINE.

THOUGH not in the habit of noticing the examinations and festivities of medical schools, either in town or country, we must say that we have been much gratified with the late proceedings at Birmingham, an account of which has been forwarded to us. Sir Earleley's Wilmot's gold medal was adjudged to Mr. Elkington, and Mr. Cox's to Messrs. Horton and Minster. Nine silver medals were distributed. The dinner went off with great éclat.

DEATH OF SPRENGEL.

KURT SPRENGEL, the eminent historian of medicine, and Professor of Botany at Halle, died on the 15th March last.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

—
DISEASES OF THE HEART.
—

Bertin's divisions of Dilatation.—With respect to dilatation of the heart, Bertin mentions three varieties, just as there are three varieties of hypertrophy. The three varieties of hypertrophy are, where there is dilatation of the left ventricle—where there is a diminution of the cavity—or where there is no change in it. So, in dilatation, there is dilatation without any increased thickness of the walls—dilatation with increased thickness of the walls—and dilatation with thinness of the walls. Now a morbid thickness of the walls is the same thing as concentric hypertrophy; dilatation without an increased thickness of the walls, but the walls in the same state as in health, would only be eccentric hypertrophy, because there must have been an addition of substance to the enlarged ventricle to have prevented it losing a part of its thickness; dilatation with thinness, which is the third variety, has nothing to do with hypertrophy; yet it is possible, I think, for us to be right in saying that there is hypertrophy even when the walls are thinner than usual, and that is under these circumstances—when there is great dilatation, much greater than the loss of thickness, because the dilatation and the loss of thickness should be proportionate to each other, for there to be no additional substance; but if the former be very great, and the latter by no means considerable, then there must have been an additional substance deposited.

General symptoms of Hypertrophy.—We will now consider the signs of hypertrophy. Those which are noticed by people who do not employ the ear or the stethoscope, are palpitation—violent action of the heart; and you will find in this affection, as in palpitation from most other causes, that the patient lies easiest upon his back or right side. The palpitation is felt much more (I do not mean that the heart beats harder, but the palpitation is a source of greater inconvenience to the patient) when he lies on the left side than when he lies on the right. You will find this to be the general rule; the exceptions are where there is some other cause operating particularly on the right side. In general, in simple affections of the heart itself, attended with palpitation, the patient lies best on the right side; the heart is then not so near the ribs as when the patient lies on the left side, and therefore it does not disturb the patient so much. Another symptom is difficulty of breathing, and the least motion makes the patient worse in this respect. Going up a slight ascent, or walking fast, will in a moment cause the patient to be out of breath in a remarkable manner; so that when you hear a patient say that he is out of breath when he is moving about, you should suspect disease of the heart, and investigate immediately, to ascertain if it be the case; so common is it. Then there is very frequently uneasiness in the side, and even sharp pain. Hypertrophy is so generally an inflammatory complaint, that the patients continually have pain in the region of the heart. This pain may have passed off before you see the patient; but originally, if not during the whole course of the disease, there is more or less pain in the cardiac region. Besides these symptoms, there is very frequently a disturbed pulse; the pulse is generally quicker than it ought to be, and in many cases it is likewise stronger. Frequently, too, there is dropsy, and the force of the heart is such

as to cause headache; and if the vessels of the head are weak it will cause apoplexy, vertigo, a throbbing of the temples and neck.

General symptoms not to be depended on alone.—But none of these symptoms are to be depended upon alone. You may, of course, have dropsy without any disease of the heart—you may have dropsy and palpitation without disease of the heart, but merely from its functions being disturbed. You may have a very violent pulse and strong palpitation, without any structural disease of the heart, from a mere general irritability of the whole system; and of course you may have dyspnoea also. When the heart is disposed to beat violently, whether from structural disease or not, you will have dyspnoea and palpitation. Again, as the walls of the heart may be much thickened, the pulse may be rendered small, because the cavity of the left ventricle is diminished. In the case of concentric hypertrophy, where the cavity is decreased, so little blood is sent forth at every stroke of the heart that there is not enough to cause a good pulse. The heart may beat violently, but so little blood is sent out that the arteries are not well distended; and hence you have great hypertrophy and a small pulse. Again: you may have great hypertrophy of the left ventricle, and great dilatation—an immense mass of muscular substance—so that the cavity is very much increased, and yet there may be a small pulse, in consequence of the aortic valves being diseased. Thus you may have a small pulse from two causes—from the cavity being so reduced, that notwithstanding the heart acts violently, there is little blood to go out; or from the opening being reduced so that while there is plenty of blood there is but little room for it to escape.

Auscultatory Signs.—The great means of making the diagnosis is by the application of the stethoscope. Now when any part of the heart is hypertrophied, you have a strong impulse at that part. As I have observed before, it is generally the left ventricle that is hypertrophied; and, therefore, if you place the stethoscope in that situation, the impulse drives the instrument against your ear at every stroke; and if you remove your head, you perceive that it is jerked.

Now by the cardiac region you of course know is meant the lower third of the sternum, and the cartilages of the fourth, fifth, sixth, and seventh ribs. The heart lies behind those parts. Generally, in health, the left ventricle lies behind the cartilages of the fourth, fifth, sixth, and seventh ribs of the left side; and the right ventricle and auricle under, and behind the lower third of the sternum; so that if there be a

very strong impulse at the ribs, as I have mentioned, without a corresponding impulse any where else, and this is pretty constant, you would infer that it is a case of hypertrophy of the left ventricle; but if the impulse be behind the lower third of the sternum, you would then consider it hypertrophy of the right ventricle. Occasionally the auricles are in a state of hypertrophy, but that is very rare, their disease generally being dilatation; and if ever they are hypertrophied, I believe they are almost always dilated at the same time. If there be hypertrophy of the auricles, it is eccentric—that is to say, they are dilated and thickened also; but usually they are not thickened at all, so that the disease is mere dilatation. It is in the upper part of the region I have now mentioned that you would expect a strong impulse, or any thing else that is morbid, if the auricles be diseased; whereas, it is at the lower part that you must expect any thing morbid, if the ventricles are the parts affected, the auricles being, as every one knows, at the top of the ventricles, at the higher part of the cardiac region.

There is no morbid sound from simple hypertrophy; even the natural sound of the part is diminished. If it be a case of simple hypertrophy, or hypertrophy out of proportion to the dilatation, you may have a violent impulse, but the sound of the part is generally lost—it is a dead thump, as though a sledge-hammer had struck against it from within, but was muffled. In a case of palpitation from a nervous cause, you will find every part of the heart thumping hard together—that is to say, both ventricles—and the sound is rather increased than not; the heart acts sharply, and if there be any alteration in sound it is louder than usual. But in a case of hypertrophy the impulse is great, but it is confined to the part, and the natural sound is diminished. If you attend to this, and take into account the general symptoms that I mentioned, you can seldom make a false diagnosis. If you take the general symptoms only, you may be deceived; but when, in addition to these, you find symptoms in the heart itself, you cannot be mistaken. Many cases of palpitation are called disease of the heart; but if you listen with the stethoscope, and find the impulse is only in one region, the right or the left ventricle, no mistake can arise.

Now and then both ventricles are hypertrophied, but then you have no strong impulse higher up than the situation of the auricles. Generally, however, it is the left ventricle only that is affected; and if the right be diseased, the left usually suffers with it.

With respect to dilatation, it is just the reverse. There is no increased impulse,

but an increase of sound; when one of the cavities of the heart is dilated, the sound is increased. It is not in general a preternatural sound; it may be so, but this does not arise as a matter of necessity. The natural sound becomes clearer and louder, but there is no additional impulse.

Supposing, however, the case is one of dilatation and hypertrophy, why then you have both signs united—you have a great impulse and an increase of sound; that is, provided the hypertrophy and dilatation are proportionate; but if the former be much greater than the latter, then you have a great impulse and no increase of sound. If, however, there be great dilatation and very little hypertrophy, then you have a great increase of sound. You may suppose that where hypertrophy and dilatation take place together, and the hypertrophy is such as to thicken the part, then the impulse and the sound are very great—indeed the impulse is dreadful; it causes the carotids to throb, and all the arteries in the head, so that the patient is tormented by a continual pain in the head, and is unable to lie down: he is obliged to keep his head erect, on account of the violent throbbing. In these cases, on account of the enormous increase of the muscular substance of the heart, you have a strong pulse. In very intense cases, you will see the head jerk at every impulse of the heart.

You must bear in mind the circumstance which I before mentioned, that when the left ventricle is hypertrophied and dilated together, it does not remain in its natural situation. Its natural situation is filled by it, as it was before, but the left ventricle extends much more to the right side, so that it will occupy entirely the place of the right ventricle. In such a case you will have a hard thump in the situation of the left ventricle, but you will also have it farther to the left, and even behind; and you will also have the impulse of the left ventricle under the sternum, in the situation of the right, so that you would think the right ventricle was dilated and hypertrophied also; but you find, from the strong impulse in all the arteries, and likewise in the situation of the left ventricle, that it is it which is diseased. When the right ventricle is hypertrophied and dilated, the impulse does not extend to the left side; and therefore, when you find a great impulse in the situation both of the left and right ventricle, you may infer that the thumping on the right side depends on the left.

When the heart is dilated, you of course have an additional symptom; from its occupying so much space that ought to be occupied by the lungs, you have a dull sound to a very great extent. In most persons in health, when you strike on the

cartilages of the fourth, fifth, sixth, and seventh ribs, there is more dull sound there than any where else; but if the heart be hypertrophied and dilated, then you have the extent of dull sound much increased. It stands to reason, that whenever a part is dilated, whether it be the auricle above or the right ventricle below, or the left, you will have a dull sound over the part, because there is a solid substance there where there ought not to be; and in the case of great dilatation of the left ventricle, with hypertrophy, you have a dull sound to a very great extent. The same circumstance would arise from a collection of fluid in the pleura; but when you see symptoms of hypertrophy and dilatation—great impulse of the heart, and the symptoms I have now mentioned—you may infer that the extent of dull sound arises from the great dilatation of the part.

In the great majority of cases, the symptoms of hypertrophy are in the region of the left ventricle—that is to say, at the cartilages of the fourth, fifth, sixth, and seventh ribs, to the left of the sternum, and under the sternum, and more to the left still; the impulse is very considerable, and the pulse itself is sharp, and for the most part full and strong. Just as in the case of a bellows sound, when there is an obstruction in any of the openings, it is more frequently than not at the mouth of the aorta: so, in examining the heart, it is well always to begin with the left ventricle, because in nine cases out of ten, or nineteen out of twenty, the disease is situated there. So, again, in a case of consumption it is well to commence an examination under the clavicle, because there phthisis usually commences.

In dilatation of the left ventricle, whether accompanied with hypertrophy or not, it is not an uncommon occurrence to hear a bellows sound, because, although the opening be not at all diminished, yet the cavity is increased; and where the cavity is dilated enormously, it sends forth such a volume of blood towards the opening that the latter is not capable of letting it pass, and therefore an obstruction is felt. I presume a bellows sound would arise from the dilatation of any other cavity, if the opening were not dilated also.

Sometimes in hypertrophy, without such dilatation, there is a bellows sound from the position of the heart being altered a little, and sometimes from the columnæ carneæ towards the opening being hypertrophied, so as to form a little obstruction. But the great symptom of hypertrophy is violent impulse, and the great symptom of dilatation an increase of sound, not a preternatural sound. The sign of obstruction, whatever the cause may be, is a preterna-

tural sound, but that merely shews obstruction, nothing else.

Decline of the Symptoms prior to Dissolution.—Now there is another thing to be remembered, and that is, that if you examine a person near to the close of his disease, you may find very few of his symptoms. If a person be near death, although the heart may be greatly hypertrophied, yet it may have so lost its power that it can only act with very little force, and the symptoms of hypertrophy may have diminished so much that you would hardly suspect how violent a disease the individual has had, and is dying of. So with respect to the bellows sound: it will diminish before death, because, although the opening has been too narrow, yet the heart having lost its power, sends forth so little blood towards the opening, that it escapes better than before. So, too, in disease of the heart, if you were called in just before death, you really might not be able sometimes to make an accurate diagnosis: the patient having lost his power, he is not so wholly under the influence of his disease as he was before.

Treatment of Hypertrophy.—With regard to the treatment of this disease, I have no doubt at all that hypertrophy may be sometimes cured. You find the heart, as I mentioned before, evidently in an inflammatory state. The organ, for the most part, toward the close of the disease, is not only firmer and harder than it should be, but likewise redder, and frequently there is pain in the region of the heart, and even pericarditis also. Now if you make a person live on low diet, if you cup repeatedly over the heart, keep him perfectly still, and relieve the bowels when it appears requisite, so that there shall be no congestion anywhere, and if you exhibit colchicum, perhaps digitalis, and sometimes mercury, if he can bear it, you will see the symptoms of hypertrophy gradually decline. I have certainly known several cases, where I had every reason to believe that the hypertrophy was very great, where abstinence from meat, spirits, and things of that description—abstinence from mental excitement, abstinence from every occupation of mind which could cause anxiety, abstinence from exercise, and every circumstance that could quicken the pulse—was followed by a decline of the symptoms, and the patient has been comparatively well. This, however, requires a long time; and after the patient appears quite well, he must persevere in the general plan, though not very assiduously carried on.

Local preferable to general Bleeding.—Local bleeding, for the most part, answers better than general bleeding. It is not very safe in chronic diseases of the heart to bleed at

the arm, for now and then patients will fall into a state of syncope, and it is a dangerous thing in diseases of the heart to bleed to syncope. We have all heard of cases where a patient with diseased heart has lost more blood than was intended, so that faintness was produced even by a couple of ounces, and the individual has died. A remarkable instance of this kind happened within the last two years. A distinguished personage, labouring under disease of the heart, was bled at the arm, and the bandage slipped, and although it is said that a few ounces only escaped, yet he fainted, and died. It is, therefore, more safe to take blood from the heart itself, by means of cupping or repeated leeches, than to bleed at the arm; for it is dangerous to induce syncope. If you do bleed generally, as you often may with perfect safety when the patient is strong and hearty, it should not be to the extent of syncope, because patients with diseased heart will sometimes die suddenly; indeed it is not an uncommon occurrence, and they die more frequently than not through syncope.

Morbid Appearances arising from Dilatation.

—In the case of dilatation, the heart is generally found soft, and paler than natural. More frequently than not, this disease depends upon debility, (though it may arise from an obstruction at the mouth of the aorta, for example, or the mitral valve,) and therefore the heart is usually found soft. When a deposition has taken place outwards, you may find the organ firmer than natural; but in a case of simple dilatation, or dilatation with hypertrophy, after it has existed some time, the reverse takes place.

Treatment of Dilatation.—Now active measures are not required in such a case as this. You have merely to bleed locally, in order to take off the congestion—to keep an open state of the bowels, and enjoin rest; very frequently, however, tonics are required. If you find the pulse soft and feeble, it would be dangerous to take away blood, the only object of venesection being to remove congestion. Leeches applied to the anus frequently answer a good purpose in such cases; but, for the most part, a strong evacuation is not at all required. When, however, there is dilatation, there is much more frequently than not hypertrophy, and a disposition to dropsy. From the dilatation, the blood is not sent out so freely as it ought to be, and consequently there is accumulation, and a tendency to morbid secretion in the cellular membrane and in the serous cavities, so that great congestion takes place in the liver, and likewise in the head, and there is also a tendency to general effusion. Such being the case, you will find it of very great use to give diuretics, and a combination of

three or four, as I formerly mentioned, is best. Squills, digitalis, and acetate of potash, answer very well: in fact, I do not know any thing so good; they answer far better than hydrogogue purgatives. You will see patients relieved exceedingly by measures of that description; but if the patient be at all weak, you will find it serviceable to give iron, and I believe the best preparation is the tartrate, because in conjunction with other means, it has a tendency to increase the flow of urine and the discharge from the bowels. I have seen patients with every symptom of dilatation of the heart lose the greater part of these symptoms, and be able to go about, after taking the tartrate of iron. It may be given in large doses, as I formerly mentioned; in fact, instead of a few grains, you may give a drachm, or even two, twice or thrice a day; but still you cannot give it in such large quantities as the carbonate, because it is apt to purge and to pinch—to do something more than carbonate or oxyde of iron. You will find many persons who cannot take more than a drachm. When it is mixed with treacle, it opens the bowels, causes an increased flow of urine, and strengthens the patient. If it purges too much, it is a good plan to mix an equal part of carbonate with it.

In such cases, I should give this tonic in preference to all others, because I know from experience that it answers so much better than others. You will see many cases of hypertrophy with dilatation where the patients are in a state of anæmia—in a leucophlegmatic condition—and if you take blood away, you find it watery, and you make the patient worse. When patients are in a state of anæmia, where it has been induced by bloodletting, or that peculiar state in which the blood is not properly manufactured, the pulse will become sharp; and so in disease of the heart you will sometimes have a sharp pulse, with great debility of the patient. Now whenever I have seen this condition united with disease of the heart, I have abstained from evacuations, given preparations of iron, and have found the patients improve. But if you notice a tendency to effusion, as shewn in the ankles, or if you hear mucous or other rattles in the bronchiæ, you will find diuretics of essential service; if there be general paleness and debility, then iron especially is one of the best things that can be given; and if the debility be very great while you give diuretics, you should exhibit the tartrate of iron, which is both a diuretic and a tonic. With such treatment as this, it is wonderful how much good may be done. You may certainly cure some cases; and even where the affection is very severe, so that cure is out of the question, you may still

do a certain portion of good—you may make the patient feel better than before, and may prolong life. It is our business to protract life, whether it is desirable for the patient or not. It is our business to act upon a general rule, and endeavour to prolong life, without considering for a moment whether the individual would be better out of the world than in it. If you treat all these cases antiphlogistically, you may do harm; when there is a state of anæmia, the adoption of such measures would be madness; the administration of iron, and even good nourishment, is then the proper treatment.

ANEURISM OF THE HEART.

Occasionally it happens that dilatation of the heart is partial; I do not mean affecting only one particular cavity, but only one particular part, or particular parts of cavities. This disease is, properly speaking, aneurism of the heart. You are aware that if only a particular spot in the whole circumference is dilated, so that a pouch is formed, it is termed *aneurism*. Occasionally all the coats dilate together at one particular spot, and form a pouch; and occasionally the inner and middle coats only are destroyed; but in both cases it is called “aneurism.”

Former erroneous application of the term.—Now in the case of the heart, the same thing will occasionally happen—there will be dilatation at one particular spot. The word *aneurism* was formerly misapplied with respect to the heart—a dilatation of the whole cavity receiving that appellation. You will find that, in some books, dilatation of the left ventricle is called “aneurism.” If there were dilatation with thinness, it was called *passive* aneurism; if there were increased thickness united with the dilatation, then it was called *active* aneurism. These expressions ought now to be dropped; but you will find them employed in this way in Corvisart’s work on Diseases of the Heart, which, at the time it was published, was a very good one.

You will find a case of true aneurism of the heart, or dilatation at one spot, so as to form a pouch, mentioned by Dr. Baillie, and several instances of it have now been collected.

Situation at which it occurs.—It occurs, like all other diseases, more frequently on the left side of the heart than on the right, and of course principally in the left ventricle. Aneurism is in itself a disease of the arteries, and therefore there is strong reason for presuming before hand, that aneurism of the heart would take place on the arterial side of the organ. I am not aware that any instance has been known of the disease occurring in the right ventricle; I believe that, in every case upon

record, you will find that it took place in the left. I have, in my work on Diseases of the Heart, referred to every case of this disease that I could find upon record up to the time I published. The affection occurred once in a patient of my own.

Most frequent in Males.—Now you are aware that aneurism of the arteries occurs much more frequently in males than in females, and that is the case with the disease under consideration; in fact, I only know of one instance on record in which it occurred in a female. The situation of it in the left ventricle is various. In some cases, the pouch has been at the apex of the ventricle, and in others—quite as numerous—it has been at the base. Sometimes it has been found between the apex and the base.

Symptoms not known.—The symptoms of the disease are not known. In the case under my care, I had no idea of the man's affection at all; I only felt satisfied that he had disease of the heart. At one time I thought it was upon the right side, and at another on the left. Accordingly, as the disease increased, it extended, and did not remain in its original spot. Dr. Baillie says that the symptoms are similar to those which characterise aneurism of the arch of the aorta, but that is saying nothing, because the symptoms of the latter affection are dyspnoea, and more or less pain at the spot; but a thousand things will give rise to those circumstances. Dr. Baillie says that the pulse is irregular; but he adds that it is often regular, and therefore that also amounts to nothing. In such a case, you will usually discover that the person has disease of the heart, but not always, because the affection has occurred in individuals in whom disease of the heart has not been suspected. Once, however, I met with this affection in the left auricle; but I have never seen such a case on record. I lately saw in some museum a preparation of this description. In the case I met with myself, the left auricle was dilated into a pouch, and the pouch was lined with layers of fibrin, exactly like aneurism of the aorta. It was not merely coagulum, but the fibrin was organized. In this case, also, I had no idea of the man's disease. I knew that he had disease of the heart, and I thought it was dilatation of the ventricle; but as to this particular affection of the auricle I confess I knew nothing about it. Whether I should now be able to discover this disease in any way, I cannot tell, but I should think I could not, even though I have had longer experience.

Not invariably lined by a smooth membrane.—In aneurism of the left ventricle, the pouch is sometimes lined by a smooth membrane, and sometimes not, and there-

fore aneurism of the heart follows the exact rule of aneurism of the aorta. You are aware that in the latter, sometimes the inner coat is not injured at all, but the three coats are all dilated together at one spot, so that you find the pouch lined by a smooth membrane. Sometimes mere pouches are formed in the heart—a mere dilatation has existed, and sometimes you will find no lining membrane at all, the inner membrane of the heart having been destroyed. The heart, therefore, is subject to aneurism, both true and false, exactly like the arteries; but instances of the disease are very rare.

INDURATION AND SOFTENING.

With regard to induration and softening of the heart, I may remark that sometimes, when the organ is hypertrophied, it is indurated, and sometimes I have seen induration without hypertrophy. When the heart is softened, it is generally dilated, but this is not always the case; if softening, however, have existed long before death, I cannot but suppose that dilatation must be the consequence. Induration, therefore, is rather allied to hypertrophy of the heart, and softening to dilatation of it. Hypertrophy is generally an inflammatory disease—a disease, at any rate, of over nourishment, and therefore you may suppose that the organ will in time become firmer than usual; whereas dilatation is rather a disease of debility, and therefore you must suppose that in many such cases the heart will be soft; before death, however, a heart that is hypertrophied may become soft.

Symptoms and morbid appearances.—I do not know any particular symptoms of induration of the heart, but if it result from an inflammatory state, you may expect long continued violent action of the heart, and a strong pulse. When the heart is softened, the pulse is generally feeble; and after death, there is frequently a quantity of bloody fluid found in the pericardium—the softened condition of the organ having allowed the blood to exude from the vessels. Sometimes, when the heart is indurated, it is not redder than usual; on the contrary, it is rather pale, and this is sometimes the case when it is softened. In carditis—true inflammation of the substance of the heart—such congestion takes place that the organ is dark coloured, and usually it is soft.

ABSCESSSES AND ULCERATION.

Occasionally we see abscesses in the heart, and I believe that for the most part they occur not very far from the pericardium outside, or the lining membrane within. It is said that they may occur in the middle of the substance of the heart,

but I rather doubt that; I think they begin in the situation I have stated.

Occasionally ulceration is seen without an abscess. Of course, when an abscess exists, it may go on to ulceration, and ulcerate through the pericardium or lining membrane; but sometimes ulceration appears to begin in the lining membrane itself—at least a little superficial ulceration is seen, without any collection of matter.

RUPTURE OF THE HEART.

When an abscess has proceeded to any extent, of course the heart is very likely to rupture, and therefore rupture of the heart has sometimes been seen after an abscess. Sometimes, however, the organ is ruptured without any abscess whatever, and without any particular deviation from a healthy structure, unless it be softening. I never met but with one case of rupture of the heart, and in that instance the organ was very soft. It occurred in a gentleman who, I believe, was a proprietor of this University, a very respectable medical man in this neighbourhood, about 60 years of age, and corpulent. He had three attacks of pain about the præcordia, accompanied with dyspnœa and palpitation; but he had gone out as usual in the intervals. One morning, however, a fourth attack of pain took place in the region of the heart, and he rang his bell for his assistant, who wished him to have a fomentation. The assistant left the room, the gentleman rang his bell violently, and before the assistant could get up to him he was dead. On opening him, I found a zig-zag fissure in the front of the heart in the left ventricle.

The greater number of instances of this disease have taken place towards the apex of the heart. It is the apex which is thin, and when the organ grows very thin, or very soft, rupture usually takes place there, or not very far from it. This accident occurs far more frequently in the left ventricle than any where else; but it may occur in any part of the heart. Some persons have supposed that it always takes place in the left ventricle, but you will find instances of its occurring in the right. George the Second died of this affection. He fell down one morning at Kensington, the sergeant-surgeon was sent for, and he attempted to bleed him, but could not; and on opening him they found that the heart was ruptured, and had let forth a quantity of blood. It is rather singular that one of the same family (the Princess of Brunswick) died, twenty years before, of the same affection; and not only was there rupture of the heart, but rupture of the right ventricle. I recollect being asked once whether a person could mistake syncope for apoplexy, and I referred to the particular case of George the Second.

His Majesty fell down senseless, and the sergeant-surgeon bled him at once; evidently presuming that it was a fit of apoplexy. Had he supposed the case to be one of syncope, he certainly would not have bled him—or at least have attempted it.

RUPTURE OF THE VALVES.

Occasionally the valves give way suddenly. A valve has been torn under a very violent effort, and very distressing symptoms have taken place. Great pain has generally been felt; but if not, great dyspnœa and great rapidity of pulse: of course I mean if the rupture be extensive. If it take place slowly, there cannot be these sudden symptoms. Sometimes, from mere intensity of disease, the valves will become exceedingly fragile, or thin, and will give way without any effort, just as the heart will do from extreme softening; but sometimes, on the other hand, they will give way under a violent effort. In one of the numbers of the *Medical Gazette* there is a very well marked case of rupture of the tricuspid valve, in which great rapidity and irregularity of the pulse took place, and I presume dyspnœa. The patient died six or seven days afterwards. Death does not always immediately ensue on rupture of the heart, when it arises from an internal cause; it may take place instantly, and generally does, but sometimes it does not take place for several hours. In the case of the valves, however, a patient may not only live several hours, but for several days; and, for what I know, a much longer period than that. A very slight degree of rupture of the valves may only keep up a considerable irritation, and the patient may die from its ill effects at a very distant period. One author mentions an instance which occurred after a fall on the right side of the chest, and death did not take place for five months; yet it was found that an aortic valve was torn.

Sometimes, instead of the valves themselves, the cordæ tendinæ have been found ruptured.

GANGRENE.

I have never seen gangrene of the heart. Cases have been supposed to be gangrene of the heart, but I should imagine they were only instances of extreme congestion of blood, which have been mistaken, by uninformed persons, to be gangrene.

OSSIFICATION.

I mentioned that the pericardium, like other serous membranes, is sometimes ossified; but, generally speaking, I believe it is not the pericardium itself that has suffered this disease, but the subserous cellular membrane immediately below it—as in the case of the pleura. But now and

then this ossification has been very extensive, and in proportion to that has the muscular substance beneath been atrophied—wasted away; and I believe this is the nature of those cases which have been called “ossification of the heart.” Bone has been deposited under the pericardium, or perhaps under the lining membrane within, and the muscular substance has wasted; so that the heart has been found little more than a shell. Mr. Burns, in his work on Diseases of the Heart, mentions an instance where the ventricles were little more than shells of bone. He says that no one ever saw complete ossification. From the progress now made in morbid anatomy, I have no doubt that there are instances of a deposition of bone external to the muscular substance, and a wasting away of the muscular substance itself.

OSSIFICATION OF THE CORONARY ARTERIES.

It is a much more common occurrence to see the coronary arteries ossified; indeed they are very frequently so. The most frequent situation of bone about the heart, is at the mitral valve and the beginning of the aorta (we consider the beginning of the aorta as a part of the heart), and next to that, ossification of the coronary arteries.

ANGINA PECTORIS.

Symptoms.—Now it has been supposed that ossification of the coronary arteries, or at least a degree of induration amounting to cartilage, gives occasion to the symptoms called *angina pectoris*. By *angina pectoris* is meant a sudden violent pain in some part of the chest near the heart, and especially at the sternum; this pain causing the patient to stand still if he be walking, and inducing a sensation as if he were about to expire. The pain at first is felt only at one spot, in the situation I have mentioned; but at length it extends to the shoulder, darts through to the spine, goes down the arm, and occurs at the end of the fingers, in general being confined to the left side, though there are a few cases where it has extended to the right shoulder, and down the right arm, and even down the front of the loins; but that is usually after it has existed some time, longer or shorter, at the sternum, and down the left arm. There is not necessarily palpitation; you may have the affection without any palpitation. Dr. Haygarth, of Bath, has collected a vast number of cases of this description, and has inferred that these symptoms are characteristic of disease of the coronary arteries: he does not say of ossification, as some make him say, but disease of those arteries, whether

it be induration, or the formation of cartilage or bone. But it is now ascertained that this disease does not characterize any particular affection of the heart. You may have it without ossification, or any perceptible disease of the coronary arteries; and, on the other hand, you will frequently find ossification of the coronary arteries without the symptoms called *angina pectoris*. You will find *angina pectoris* very well described by Dr. Heberden, in an early volume, the first or second I believe, of the Transactions of the College of Physicians. It is not one of the common symptoms of disease of the heart; in the greater number of instances of this affection, whatever it may be, you have not the symptoms of *angina pectoris*; and although it is a fact that you frequently have these symptoms when there is ossification of the coronary arteries, or great ossification of the mouth of the aorta, yet you may have them in almost any disease of the heart whatever, and also without any ossification at all.

Such symptoms, it is well known now, will take place without any disease of the heart; in fact, some cases were published a few years ago, which were accurately described as *angina pectoris*, but in which no disease of the heart was found after death. The truth is, that gastrodynia, spasmodic pain of the stomach, I believe, frequently resembles this affection. The left side of the stomach is situated close to the heart, and a violent pain of the stomach frequently shoots upwards; frequently it will shoot as far as the shoulder, and even down the arm. In cases of pure spasmodic or neuralgic pain of the stomach, which will give way to stramonium, prussic acid, and remedies of that description, and which are shewn to be diseases of the stomach, not only by their ceasing entirely on the exhibition of remedies calculated to relieve functional disorders of the stomach, but by acidity, perhaps vomiting, and various other symptoms indicating disease of the stomach and not of the heart, I have known persons seized with a violent pain when they have moved quickly, just the same as when there has been disease of the heart itself. The heart is certainly subject to pain of a neuralgic character. I have seen several cases of persons who have had violent pain at different times in the region of the heart, and the difference between it and what is called *angina pectoris* I have found to be this—that the latter is only felt when the patient moves about, whereas a neuralgic pain is felt quite as severe when the patient is sitting still; frequently, too, there is pain darting in other distinct nerves of the body. The pain is of a stabbing character; and although it may be made worse by the patient jolting himself about, yet when he is

perfectly still it will frequently come on in the most violent way. Another diagnostic mark is, that neuralgia is not particularly disposed to dart through the left arm, nor is it attended with a dying sensation, as though the individual were about to expire.

Treatment.—In regard to the symptoms called angina pectoris, I have relieved them more by prussic acid than any other remedy. If there be organic disease of the heart, you cannot relieve it to the same extent as a neuralgic affection of the organ, and I do not know that I ever did particular good in such cases.

OTHER STRUCTURAL DISEASES.

There are certain other structural affections of the heart, not to be known by any particular signs.

I have seen the substance of the heart apparently changed to fat. I recollect opening an individual, in whom there was merely an extreme thin layer of muscular substance on the outside of the heart and within, and when we had cut through this, the rest was all fat. The individual had laboured under great difficulty of breathing, dropsy, and acute attacks of syncope. The heart was not able to do its duty. He was known to have disease of the heart for many years, but no one could imagine the real nature of the disease. Stagnation of blood took place in various parts, and there was dropsy and fainting. You will find a few other instances of this affection recorded in the Dublin Hospital Reports, and the Edinburgh Medical and Surgical Journal. This is different to those cases where fat is deposited outside the heart; the heart is replaced sometimes by fat.

Occasionally the heart is scrofulous; I have seen scrofulous tubercular matter in its substance.

The heart is said, though I have never seen it, sometimes to be in a cancerous condition, and it will contain cysts, and they say even true hydatids. Sometimes the heart has melanotic deposits, but I have never seen that affection.

The heart will sometimes waste away, be atrophied; and then it generally looks pale and wrinkled, and is compared by Laennec to a shrivelled apple. You will frequently find this to be the case in phthisis, but occasionally it occurs independently of that complaint. You are not, however, justified in saying that the heart is atrophied because it is small; for it may have contracted, and you find that the walls are thick in proportion as the organ is small. I mentioned that the walls being thick is not sufficient to warrant you in saying that there is hypertrophy; in order to constitute hypertrophy, there should

be no diminution of bulk in proportion to the increased thickness. So, on the other hand, there is no reason to say that the heart is wasted because it is small; in order to constitute atrophy, there must be no increase of thickness in proportion to the diminution of the cavity.

Occasionally, the heart, when it is wasted, does not become smaller; the bulk remains the same externally, but all the walls have become thin. The cavity has increased in proportion as the walls have become thin, but there has been no increase of the external surface. This is an instance of atrophy, just the same as when the whole bulk has been lessened together.

I once opened a very curious case: there were small globular cysts, each containing bloody fluid, and which were attached by peduncles to the inner surface of the heart. They did not hang into the cavity, but existed between the *columnæ carneæ*, and were seen pressing the ventricle out. It is very singular, but it occurred in the individual in whom I found for the first time in my life—before I heard of such a thing—what is called “pulmonary apoplexy.”

You will continually, on opening a heart, find a large coagulum of fibrin—pure fibrin, the red particles being altogether separated. These coagula are called in common language, or at least were called, *polypi*. We do well to get rid of such absurd names. This fibrin was supposed to have existed during life, and to have indicated great disease, but it is now known to be merely a separation of the red particles. Occasionally, however, this does exist during life; and I presume the mode of distinguishing it will be to observe whether the coagula are organized and adherent to the substance or not. If you see that these coagula of fibrin are organized, really vascular, adherent to the sides, not merely sticking among the *columnæ carneæ*, but attached by real adhesions, then you may suppose that they existed during life. Instances have occurred in which the symptoms were decidedly referrible to these coagula, where the course of the blood was obstructed without any one knowing the reason why, and where a bellows sound was heard, but after death a coagulum of fibrin was found adherent, perfectly united to the substance of the heart. I once met with an instance myself where a large portion of fibrin was adherent to the mitral valve, just in the same way as an adhesion will exist in the pulmonary and costal pleuræ.

CAUTIONS AS TO DIAGNOSIS.

You see, therefore, that there are a great number of organic diseases of the heart which give no sign to the ear; but while you have no right to say that there is not organic disease of the heart, I do not

know that you are justified in any case in saying that there is. There is no sign of scrofula of the heart, no sign of cancer, no sign of abscesses in it. A number of changes may take place in the heart of a structural nature, and yet give no sign that the ear can appreciate, and may only disturb the functions of the organ in such a way that you are almost at a loss to say whether there is functional or structural disease. One is never justified in saying to any individual that he has not structural disease of the heart; you may say that the symptoms you observe do not indicate it, and you may say that such and such a structural disease does not exist, but you cannot affirm that there is no structural disease whatever.

ANEURISM OF THE AORTA.

There is disease of another part which it is right to mention as a part of the heart. It is situated in the chest, and is an affection of the ascending aorta, particularly of the arch. These are parts which are very frequently diseased, and we have continually to make a diagnosis between affections of them and of the heart. The most common disease of the aorta is, of course, aneurism or dilatation. We continually find on opening bodies, that while there is disease of the heart itself, there is disease of the aorta also. The inner surface is rough, perhaps studded with a yellow opaque substance, perhaps with bone, and frequently the inner coat is destroyed here and there, so that there is rough bone, which the blood passes over. When the inner coat is destroyed, an appearance very much like ulceration is seen. You will sometimes see the inner surface of the aorta rough, like the bark of a tree, between the yellow deposit and the bone itself.

Of course there is no sign which will indicate this affection. It rarely exists alone, but is generally found united with disease of the left ventricle. Disease of the left ventricle will, however, exist without it, and it may take place independently of disease of the left ventricle.

The aorta, where it arises from the heart, is frequently dilated; and besides being dilated, it is frequently distended at one spot or more into a pouch, so that an aneurism exists. There is seldom an aneurism of the ascending aorta without a dilatation—that is to say, the whole circumference of the ascending aorta dilates in the first place, and then in the midst of the dilated vessel you see at one spot a pouch formed. Aneurism very rarely affects the ascending aorta without the vessel having been first dilated.

Aneurism of the ascending aorta fre-

quently exists without people being aware of it, and they will fall down dead in a moment, as if they were shot, nobody imagining what is the matter; and at the autopsy, the aorta is found ruptured into the pericardium. I had a striking instance of this in a woman who came into the hospital with a pain in the neck, face, and shoulder, which appeared to be rheumatic. Leeches were being applied, she shrieked, fell back, and was dead in a few minutes. On opening her, I found that the pericardium was filled with blood. In these cases, on cutting the pericardium, out flows a quantity of bloody serum; then, after that, you find a coagulum of blood, and then you observe a fissure in the aorta; first in the pericardium; and under that again you generally find a transverse fissure. In this case, the inner and the middle coats had given way some time before; a great quantity of blood was effused, the coagulum was organized, and, as in common aneurism, it pushed out the external coat, which suddenly cracked, and she instantly expired.

It very often happens, as I have mentioned, that patients die of rupture of the aorta into the pericardium without the patient knowing previously that there is any thing at all the matter; but if the disease be situated a little higher than that, then you have certain symptoms induced.

Symptoms.—Supposing that the disease is situated in the ascending aorta after the vessel has left the pericardium, the patient then frequently complains of pain at that particular spot; and on listening, you hear a certain loud sound at the stroke of the heart—at the time of the pulse, and this long before it has produced a tumor. When the aneurism has attained a certain size, it generally produces a tumor on the right side, about the fifth or sixth ribs. The symptoms of disease of the heart are at the sternum on the left side; but in the case of the ascending aorta, they occur on the right side. If the disease be situated higher up still, in the arch itself, you have the tumor in the situation of the third or fourth ribs. If it occur in the superior part of the arch, then you have the tumor above the sternum at the clavicle. Now when there is a tumor, it pulsates very strongly, and there are general symptoms. There is frequently cough, frequently mucous and bloody expectoration, and sometimes there is difficulty of breathing. The dyspnoea is sometimes so great that the person cannot lie down, and sometimes there is difficulty of swallowing. If it so happen that the œsophagus is pressed upon, the compression is frequently such that it produces spasmodic asthma. You

have pain at the right shoulder, pain down the right arm, and pain at the right side of the head. Under these circumstances there can be no doubt whatever as to the nature of the disease.

I have found that I have been able to discover this affection by hearing a loud sound in these parts. Bertin said that it could be discovered, but Laennec said it could not. Bertin, however, replied that Laennec did not apply the stethoscope in the right place; that he should have applied it over the sternum, and then in the incipient stage he would have heard a loud sound. I certainly have heard at that part a loud sound, louder than at the heart itself; and when the patient has had difficulty of breathing and cough, such symptoms as might arise from aneurism, I have suspected aneurism of the arch of the aorta before there has been an external tumor.

The other day I had a case in which I was able to verify the diagnosis, but then I had something more to guide me, for there was a tumor, so that it was clear there was some disease in that quarter; and therefore I did not pretend to be very sagacious in making out that the arch was dilated. If, however, there be no tumor, so that there is nothing to guide you but the ear, I should think the diagnosis would not be very certain. Occasionally you hear a bellows sound, just as in aneurism of other parts, and sometimes you have a double sound, exactly as in the case of the heart, and for this reason you hear the sound of the heart and also the peculiar sound of the aneurism.

Treatment.—As to the treatment of a case of this description, of course nothing can be done but to enjoin perfect rest, and deprive the patient of all stimuli, giving him that nourishment which is least likely to quicken the pulse. Bleeding from time to time is exceedingly useful; you will find that you relieve the sufferings of the patient exceedingly by bleeding him. You know that in aneurism, nature fortifies the part by producing adhesions around it; but there is frequently more inflammation than is useful, and there are frequently pricking, stabbing pains, together with violence of the heart's action, and all these are, of course, diminished by bleeding. You will find the blood buffy and cupped in such cases, because there is inflammation going on. It is of the greatest use to bleed from time to time, and keep the patient low and quiet. These are not cases to be neglected: one may not be able to save life, but we may diminish the pain very much.

GULSTONIAN LECTURES, 1833.

—
ON THE

FUNCTIONS OF THE ABDOMEN,

AND SOME OF THE

Diagnostic Marks of its Disease.

BY RICHARD BRIGHT, M.D. F.R.S. &c.

LECTURE III.

YOUR attention has hitherto been directed to various points of diagnosis connected with the functions of the different abdominal organs, as displayed in their secretions and excretions: I now come to consider more particularly some indications derived from the examination of the abdomen itself, including—

1. The sensation, whether morbid or natural, of the skin.
2. The external appearance of the skin as to texture, colour, vascularity, and marks.
3. The form ascertained by sight.
4. The sensation communicated to the touch in diseases external to the cavity of the abdomen.
5. The sensation communicated to the touch by internal disease.
6. The sound ascertained by the application of the ear.
7. The sound elicited by percussion.
8. Pain produced by pressure.
9. Pain experienced independently of pressure.

Each of these presents to us various circumstances from which, either alone or in combination, we are enabled to approach with more or less certainty towards a knowledge of the nature and situation of the disease.

First,—the sensibility of the skin varies much under different circumstances. In fever it is often greatly increased, so that were the hand applied to the abdomen alone, we should be misled into the belief that some specific disease existed in that part; whereas, upon further inquiry, we shall find this excessive sensibility to belong to the abdomen in common only with the whole surface of the body; and this, together with the febrile aspect and symptoms, will point out its real nature. In some cases of neuralgic affection connected with hysteria, we have the most acute sensibility over various parts, and this not unusually occurring on the abdomen in a more decided manner. This neuralgic tenderness often assumes the hemiplegic character; and extending over the chest and arms, in this way betrays its genuine nervous origin. In rheumatism we also occasionally find superficial tenderness belonging to the muscular and tendinous structures rather than to the internal organs, or to the integuments. At other

times we have the sensibility of the skin over the abdomen diminished, as in cases of paralysis, whether from cerebral or from spinal disease. Painful sensations are likewise experienced in various parts of the body, but more particularly of the abdomen, in connexion with hysteric neuralgia, and these sensations often so decidedly referred to the situation of some definite organ, as the liver, the spleen, the colon, or the uterus, that it requires all the conviction afforded by concomitant symptoms to overcome the impression which the urgent and continued complaints of the patient are calculated to excite, and it is often to the incongruity of the symptoms that we are chiefly indebted for our more correct diagnosis—a subject on which my friend Dr. Addison has published some interesting observations. There is another source of painful sensation sometimes affecting the abdomen, which is the urgent lancinating pain preceding and following an attack of herpes zoster, or shingles; and insignificant as this may appear, I have known it become a most harassing symptom, and one which has greatly confounded the diagnosis. Some few instances of faulty sensation also occur, as the burning sensation attendant on paralysis, and the itching which accompanies jaundice. It is of the utmost importance that all such morbid affections of the sensation should be retained in mind when we are investigating abdominal disease, as, without this, we shall be liable to be greatly misled.

Secondly,—the external appearance of the skin varies as to texture, colour, and vascularity. It becomes smooth, white, and shining, from anasarca and emphysema, when the accumulated serum, or the effused air, distends the cellular membrane, and drives the blood from the neighbouring vessels. It becomes smooth and red when threatened with erysipelatous inflammation. It becomes smooth, likewise, when the abdomen is distended with fluid in ascites; with air, as in tympanites; or with internal tumors of large size. It becomes rough, thrown into folds, and rugæ, when fluid, or fatty matter with which it has been distended, whether it have been internal or external, is absorbed, and the same is the case after repeated pregnancy. It becomes traversed by numerous veins wherever pressure is made on the large internal veins, and thus the return of blood is interrupted. This occurs very often in ascites, both owing to the interruption given by the hardened or disorganized liver, and by the pressure of the fluid. It also happens when the cava, or the iliac and femoral vessels, become obstructed and obliterated from inflammation, or in the course of diseases of debility. The skin of the abdomen is likewise subject, as other

parts of the body, to various cutaneous affections, both acute and chronic, and is occasionally the seat of many marks, from the application of cupping-glasses, leeches, blisters, and irritating ointments, which lead the physician to various conclusions regarding former diseases, or the views of those under whose care the patient has been treated.

The skin is also tinged with different colours in connexion with other disease, as the sallowness depending upon disease of the spleen, or the colour in jaundice, whose various shades of yellow afford considerable information to the experienced physician. And upon this subject I shall make a few remarks, that I may draw your attention to some of the circumstances in connexion with colour, which, in jaundice, assist us in forming a conjecture at least regarding the cause upon which the jaundice depends in any particular instance. It is not, however, entirely from the intensity of the colour that our inferences must be drawn, though this is one important subject of consideration, but we must likewise take into account the mode of attack, and the progress of the discolouration, the age of the patient, the evidence to be derived from tumor, the proofs of concomitant or previously existing disease in other organs, and the existence of pain, either spontaneous or consequent upon pressure. The first and most prominent symptom, however, that which immediately strikes the eye in jaundice, and from which the disease derives its name, is that which is more particularly at this moment brought under our consideration—the colour of the skin. This varies, from the faintest tinge of yellow running into a decided lemon-tint, to the deepest shade of the same colour, which, mingled with the flush of the fevered cheek, amounts to a deep orange colour, or, combined with the dingy aspect connected with age and emaciation, assumes a colour bordering on green. The discolouration of the skin is sometimes quite sudden, so that a single night has been sufficient for the production of the decided effect in its most marked and severe degree. More generally two or three days elapse before the colour is such as to allow us to characterize the appearance by the name of decided jaundice, and sometimes it creeps on so imperceptibly, that scarcely, after the lapse of weeks, do we feel authorized in designating it by any other term than that of sallowness. From these circumstances alone, connected with the colour of the skin, and putting all other symptoms out of view, we are able to form some conjectures regarding the source of the disease, and the state of the liver:—

1st. If the colour is very intense, we are

pretty certain that a large portion of the liver retains its healthy power of secretion.

2d. If the intense colour have been very suddenly produced, we have reason to believe that some sudden cause of obstruction has occurred, as a small calculus impacted in the common duct; or that some unhealthy action is going on in the liver, which, while it does not prevent the secretion, or perhaps increases it, greatly favours the absorption of the bile; and this action is probably of the character of inflammation.

3d. If the colour be intense, but have come on very slowly, we have reason to think that the obstruction is local, and not such as to interfere with the healthy secretion of bile, but that it has gradually effected its retention in the liver.

4th. If the colour be faint, confined to a light lemon hue, we may infer that the obstruction is not complete, or is accompanied by a considerable deficiency in the power of secretion; and if this light sallow colour have been long establishing itself, the inference is, that the liver itself is extremely disorganized.

5th. If the colour have been subject to sudden alternations, so that it has been decided one day, and after a day or two has disappeared and reappeared, these changes are generally to be ascribed, either to the presence and displacement of biliary calculi, or the passing of numerous small ones, or to some intermittent action analogous to the remission of fever; or when the changes have been slower, they may be attributed to some irregular growth or disorganization of the nature of tubera or hydatids, obstructing the ducts through small portions of the liver, at first partially, so as to allow of excretion, which, after a time, is entirely prevented.

Such, then, are at least some of the inferences fairly deducible from the colour of the skin, which, if not always correct, are at least so far important as they seem to confirm or modify the opinion we may be led to form from other sources of diagnosis, to which it is not right that I should now more minutely refer.

Thirdly,—the form which is ascertained by the simple inspection of the abdomen varies considerably, and affords important information, at least serving to direct our further inquiries. In ascites, if the accumulation be great, we have one general tense cylindrical, or ovoid figure; if the effusion be less, we see the swelling increasing more towards whatever part is most depending. In tympanites the abdomen is often greatly distended, but projects in the course of the different intestines, producing an uneven swelling, and often divided by some portion much less distended, so as to present the appearance

of two or three irregular elevations corresponding with the arch of the colon, the stomach, or some other portion of the alimentary canal; and in cases of considerable emaciation, these swellings are seen plainly, assuming the forms of the different convolutions of the intestine; and when the peristaltic force is great, the motion produced by the muscular contraction is distinctly seen. This usually happens in cases where some stricture or mechanical obstruction has long existed, calling, therefore, the muscular action into frequent and excessive exercise, and it affects those parts which are above the stricture; thus I have seen it well marked in two cases of stricture in the lower part of the small intestines, and also as affecting the stomach in a case of long continued scirrhus of the pylorus.

When an accumulation of adipose matter in the omentum or mesentery occasions the increased bulk of the abdomen, we generally perceive an even round projection, greatest in the upper part. If the fat be external to the cavity, the substantial rolls it forms, and the way in which it surrounds, more particularly the umbilicus, gives a peculiarity to its character.

When anasarcous fluid occupies the meshes of the cellular membrane, the swelling is very seldom confined to the space covering the abdomen; and when it is excessive, generally by gravitation or by pressure, manifests its peculiar nature by the irregular swelling which it produces.

Hydatids give rise to swellings of the most irregular forms, projecting in all parts of the abdomen, so as frequently to become obvious to the eye. When the hydatids are very numerous, or occupy the omentum, they distend the abdomen to an enormous size.

Ovarian tumors, according to their varied forms and structures, produce great variety in the appearance of the abdomen. In general, till they are greatly advanced, they render it uneven in its enlargement, and shew themselves as ascending from the lateral parts of the pelvis.

The enlarged uterus is distinguished by its situation, forming a distinct tumor in the centre of the abdomen, rising from the pelvis.—The liver shews itself by the full cushion-like enlargement of the upper part of the abdomen, generally at first towards the right side, but gradually extending towards the left, and proceeding even below the umbilicus.—The spleen, on the contrary, may enlarge till it makes the left side of the abdomen most manifestly project.—The kidneys when diseased may often be seen swelling the upper part of the iliac fossa.—The bladder is found distinctly raising

the pubic region, and sometimes enlarging the middle of the abdomen as high as, or even above the umbilicus, still preserving its ovoid shape.

Fourthly,—sensation communicated to the touch from the state of the surface, or the immediately subjacent tissues, is capable of conveying much more exact and definite information than simple inspection. The surface may be shrivelled, rough, smooth, hot, or cold, as indications of superficial, deep-seated, or constitutional disease; and with regard to the subjacent tissues, more important changes may be recognized.—In its natural and healthy condition, the skin is elastic, from the healthy supply of the fatty and serous secretions;—in obesity it becomes hard, resisting, and coarse-grained;—in attenuation it loses its fatty matter, and in part loses its elasticity;—but still further does it lose its natural elasticity in cases where the due quantity of serous secretion is carried off, as in cholera.—In elephantiasis, and some other morbid changes which affect the cellular membrane, it becomes hard and unyielding, a condition which I once saw most remarkably exhibited over the whole surface in a man who, after passing many months as a sailor on the coast of Guinea, was called to the North American station, and in him not only the cellular membrane of the abdomen had acquired a peculiar hardness, but almost all power of expression was lost, for his face and his fingers were so stiff and immoveable that I believe it would have been more easy to break than to bend them.—In anasarca the skin is soft, yielding like dough to pressure.—In emphysema it is more elastic, affording a peculiar crepitus when pressed. This condition of the cellular membrane is generally produced from mechanical injury to the lungs by fractured ribs, but I have seen it occur more than once from ulceration produced in the course both of phthisis and of empyema.

In the carcinomatous diathesis we often find the whole, or part of the abdomen, presenting a knotty feel, from hard, round, or oval glandular bodies, beneath the skin, and the same in melanosis; and we are sometimes enabled by this symptom to ascertain the existence of malignant diseases in internal organs, where they have otherwise been undiscovered. I have discovered, for instance, scirrhus disease in the rectum from this knotty feel in the groins. When the true malignant disease was going on in the ovary, producing adhesion to the parietes of the abdomen, I have known these hard knots to be felt on the abdomen; and so, likewise, when the lung was affected, I have in several instances traced the same bodies on the outside of the ribs. The parietes of the

abdomen are sometimes hard and unyielding, from the state of the muscles, arising often from voluntary or semi-voluntary contraction, which I have thought more frequently connected with disease of the lungs than of the abdomen itself. The muscles are still more decidedly hard and contracted under the violent spasmodic action of tetanus, in which we sometimes find them actually lacerated.

There are, again, some more circumscribed affections of the integuments of the abdomen, as swellings arising from diffused inflammation of the cellular membrane, in the form of carbuncle, or the more limited inflammation of abscesses, either acute or chronic, which, forming beneath the integuments, are very capable of seriously perplexing our diagnosis, or the swelling of steatomatous tumors, which, on the abdomen, often attain an enormous magnitude. Some casual projections occasionally take place on the abdomen, as when fatty matter protrudes from beneath the fascia of the recti muscles, or when a hydrocele of the spermatic cord, or the different forms of hernia, push forward the integuments.

Some peculiar sensations depend on deposits taking place in the abdomen external to any of the viscera: such, for instance, is the fluid of ascites, occupying the sac of the peritoneum, and yielding a sensation to the touch, which can scarcely be mistaken. As this fluid necessarily gravitates to the most depending parts, so its situation will vary with the changing posture of the patient; and as long as the effusion is small, or even not very considerable, this circumstance must be cautiously held in view; but when the ascites is become general, it is of little importance in what position the patient is placed. The sensation of fluctuation, that to which I refer, may be distinctly felt by placing the hand on any one part occupied by the fluid, and very gently striking with the other hand upon some distant part; and the difficulty in this case will not be to detect fluid, but to know whether that fluid be in the peritoneum, or is encysted in some adventitious sac, such as in the ovarian dropsy. The indistinctness of the fluctuation, however, and the history of the disease, will generally assist in clearing up this difficulty.

Another peculiar sensation is yielded by gentle pressure on the abdomen, when fresh adhesions are forming between various parts of the peritoneum; this is an approach to crepitation—nearly the feel communicated by bending and pressing new leather. When, again, the deposit in the peritoneum is more complete and more general, the whole abdomen yields a solid dough-like sensation, or a hard knotty feel,

according as the deposit is such as only to draw the intestines into one mass, or is so abundant and so changed as to form irregular accumulations.

Fifthly,—with respect to the various viscera themselves, the hand can generally ascertain any particular organ enlarged or hardened, long before it has produced any obvious change in the appearance to the eye; but in this investigation there are two circumstances which often lead to error: 1st, the action of the abdominal muscles, which, when general, has induced the belief that the peritoneum or omentum has been thickened or indurated, and when more partial, has afforded a sensation as if the liver, the spleen, the stomach, the urinary bladder, or the uterus, had been hardened; and, 2dly, the effusion of serum into the cellular membrane of the parietes, which, by gravitation or pressure, frequently produces the most singularly deceptive tumors, under certain modifications scarcely to be distinguished as external to the abdominal muscles.

The former of these sources of error is generally to be detected by considering the situations occupied by the swellings of the recti muscles, or the transversales—by altering the position of the body—by taking an opportunity to divert the mind of the patient—or by keeping the hand some time on the abdomen, till the muscles, either through weariness, or through becoming accustomed to the stimulus, relax;—and with regard to the tumors depending upon anasarous infiltration, they are to be detected by continued gentle pressure, which seldom fails after a few seconds to produce the usual pitting of anasarca. These two sources of error being removed, each of the abdominal viscera affords to the touch some variety in the sensation it produces.

The liver in its natural state is very exactly fitted into the cavity of the diaphragm, from which it even assumes any peculiarity of surface which unusual puckering of that muscle may be calculated to impress upon it. The margin in health scarcely descends below the ribs; but under many circumstances of inflammatory action, or of congestion in the organ, it goes into a state of simple enlargement, and then its lower portion is distinctly to be felt descending below the ribs, and nearly following their course; then occupying the pit of the stomach quite to the margin of the opposite ribs. In this state of simple enlargement the surface is perfectly smooth, and it is not always easy to be certain that we are not deceived by the abdominal muscles, though the continuity of its feel, and its running backwards even towards the right lumbar region, will in general confirm the opinion we have formed.

The liver is thus often to be traced in the state of simple enlargement, but still more when affected with fatty degeneration is it to be felt descending from beneath the ribs under which it is traced, and occupying with its larger lobe the whole right side of the abdomen, quite to a level of the crest of the ilium. Its edge, as it remains perfectly acute, is perhaps not to be traced, but its unyielding structure is felt passing below the umbilicus; and on the left side—connected with this at the upper part—the left lobe is felt, descending almost to the umbilicus, and occupying the whole of the scrobiculus cordis, quite to the left hypochondriac region. The surface of the organ is perfectly smooth, and if the integuments are thin, and the muscles well relaxed, will sometimes communicate a yielding dough-like sensation; or, in that state of liver where the acini have undergone a general change and induration, this yielding sensation will be wanting; or, as this state often exists without emaciation, little more than its augmented size can be ascertained. At other times, the liver, more or less extensively enlarged, affords a distinctly uneven surface to the touch, which depends on that lobulated structure which arises from the change and contraction of the cellular membrane pervading the viscus. In this case the liver seldom descends low, being but rarely enlarged; indeed, this condition of the liver is often attended even by diminution in its size, so as to render it difficult to gain any information from the touch; but here the deformity and rounding which takes place in the thin margin, often affords a fresh indication. The liver not unfrequently presents still greater inequalities of surface to the touch, arising from fungoid disease in its various modifications; sometimes affording distinct tubera, more or less elevated, and more or less hard or yielding; at other times the round elastic feel of the tumor, which we still judge to be appended to the liver, leads to the belief of its hydatid character.

The apparent enlargement of the liver must not at all times be trusted, for it occasionally happens that disease existing within the chest, more particularly an accumulation of serum in the right thoracic cavity, forces the liver so far down, and towards the left side, that it is distinctly felt projecting below the ribs. In such cases it is only by a careful examination of the chest, both by the eye and by the ear, that the true cause can be detected.

The spleen affords fewer varieties of sensation to the touch than the liver; indeed, we seldom trace any thing beyond the simple fact of enlargement, with more or less of induration. In its healthy condition it is so completely protected by the

ribs of the left side, and is so moveable, yielding with the stomach under pressure, that we cannot ascertain its existence by the touch; but as it enlarges, we find it gradually projected from beneath the false ribs on the left side, and descending further and further, while it continues still to increase laterally, advancing towards the umbilicus, until at length it occupies the whole side, descending to the pelvis. Its general situation, its peculiar form, which may often be traced even to the irregular notching of its anterior margin, and its mobility, which allows it to fall quite away from the ribs when the patient is placed on the right side, will almost always enable us to decide on the diseased organ. The changes of structure which take place in the spleen usually produce too little alteration in its surface to be ascertained by the touch during life.

The pancreas, even when most enlarged and diseased, is too deeply seated to afford any indications to the hand, nor indeed are any of our diagnostic marks of its diseases to be considered as yet satisfactory.

The gall-bladder may occasionally be detected by the touch, when some firm obstruction has taken place in the course of the common duct, for then the bile abundantly secreted by the liver has been forced to accumulate in the gall-bladder, distending it sometimes to an enormous size, so that its fundus may be distinctly felt a little to the left of the scrobiculus cordis, or even extending low into the iliac region. This condition of the gall-bladder will generally be found to indicate disease of the pancreas itself, or of the absorbent glands lying upon it, near its union with the duodenum; and the opening of the common duct is in these cases not unfrequently obliterated.

Tumors will very often be detected in the abdomen by careful examination, which depend upon new deposits, on the peritoneum attached to the intestines or other parts, or within the folds of the omentum; and these very generally of a fungoid character. At other times the lumbar glands, or the mesenteric and mesocolic glands, and those situated in Glisson's capsule, enlarge to a great extent, either from fungoid or serofulous disease, forming knotted and botryoidal masses, which, as they occupy various situations, require that the conclusions drawn from the most careful manual examination should be assisted, contrasted, or confirmed, by a patient consideration of all the collateral circumstances; and after we have done our utmost, it is occasionally quite impossible to be certain whether the tumors thus ascertained are independent of the viscera near which they are situated, and to which they are often inseparably

attached by adhesions, though they do not primarily or necessarily belong to them.

The stomach is occasionally distended with flatus, so as to be traced pretty distinctly by the touch; at other times scirrhus induration of its substance gives a hard unyielding sensation below the scrobiculus cordis; at other times the pylorus, or the pyloric extremity of the stomach, is the seat of tumor, most distinctly to be traced by the touch when emaciation has proceeded to a great degree; and it requires much care not to be deceived regarding this tumor, for owing to its weight, to the enlargement of the stomach from over-distention, and to absorption of the fat of the mesentery, and the collapsed state of the intestines when long inanition, we find the pylorus drawn exceedingly out of its natural situation, descending to the umbilicus, and even into the right iliac region. Under some circumstances the hand will perceive the muscular motion of the stomach, a symptom generally connected with long-continued or gradually increasing contraction, organic or functional, of the pylorus.

The intestines become the subjects of investigation by the touch, when loaded with feces or distended by flatus.—When accumulations of feces take place, these generally occur in the large intestines, and give rise to massive and often irregular tumors in various parts of the course of the colon, very capable therefore of being mistaken for disease of the kidney, of the liver, of the omentum, or of the ovaries; and it is often only by the changes in situation which such tumors undergo, or by the effects of purgatives, that we are brought to a perfect conviction as to the nature of the enlargements. Sometimes, indeed, we ascertain in emaciated persons the absolute plastic consistence of these feculent accumulations, and find that the scybala are capable of being moved by pressure along the course of the intestine. The cæcum is liable to be greatly distended; and in some cases great difficulty arises in distinguishing the enlargement of this viscus from the ovarian encysted tumor. This part is likewise liable to the formation of those calculi of which I had occasion to speak in a former lecture, as being frequent in districts where oatmeal is much employed in diet. The same situation very nearly is not unfrequently attacked by swelling, from the formation of fecal abscess, often originating in irritation communicated from disease of the appendix vermiformis. The rectum is also liable to very great distention from stricture and from paralysis; and though great accumulation may take place in this intestine, without obvious external tumor, yet occa-

sionally the feculent mass rises above the pelvis, and forms a tumor which has been mistaken for the uterus in the female.—The small intestines may occasionally be detected by the touch, as loaded with half-digested feculent matter, which, in this case, yields a general pulpy feel over the whole abdomen. The presence of flatus in any considerable quantity, gives on the contrary, an elastic resistance to the hand, and the situation and extent of this sensation leads us to inferences regarding the part of the intestine which is distended; although it must be owned, that in consequence of the new situations which the intestine often assumes when greatly distended, and the occasional occurrence of considerable variety in the course of the colon, it is not always possible to rely implicitly upon the inferences which we should be inclined to draw from situation.

The hand will sometimes detect the peristaltic motion, and this more usually denotes the affection of the small than of the large intestines.

Sixthly,—sounds as ascertained by the application of the ear.—The principal cases in which the stethoscope is applicable to the abdomen, are, first, to ascertain pregnancy by the sound of the action of the heart of the fœtus; secondly, to confirm the opinion we have formed of the existence of aneurism—for when this disease is present, not only do we feel the general beating of the artery, but we feel in some degree, and much more can we hear, the vibration which communicates itself at every beat, while the blood is forced through the small orifice of the diseased artery; and, thirdly, by the sound we perceive the passing of flatus from part to part, and sometimes by the peculiar rushing sound may conjecture, at least, the nature and extent of intestinal contractions.

Seventhly,—sounds elicited by percussion.—This mode of investigation is a great assistance in confirming and modifying the conclusion to which we have been led by the sight and by the sense of touch. It is by no means necessary that we should have recourse to an instrument for this purpose, although such has been invented; the back of the finger is quite sufficient for common purposes; but when it is requisite to trace very exactly the extent of a tumor, or the situation of an inflated intestine, a little ivory plate, or (as Dr. Badham informs me, still better) a thin piece of cork, may be employed, as enabling us more exactly to define the line of separation between the dull sound afforded by fluid, the still more dead sound of a fleshy tumor, or the clear reverberation of an

inflated part. The examination of the abdomen by this method is frequently of considerable importance, and particularly when, in the operation of paracentesis, it becomes a matter of such paramount importance that no internal organ should be wounded.

Eighthly,—painful sensation independently of pressure.—The painful sensations of the abdomen are very various, arising from a multiplicity of causes. Pain may be sudden and excruciating, either from sudden spasm, as in colic, or the passing of gall-stones or urinary calculi, or from attacks of inflammation, as sometimes in gouty metastasis, or from sudden rupture of the intestine, or bursting of a cyst or abscess. Pain, on the contrary, may approach gradually, as often occurs in dyspeptic seizures, or the abdominal pains of dysmenorrhœa, and not unfrequently in the attack, or during the progress, of peritoneal inflammation. The pain may be fixed, as in the local symptoms which arise from the inflammation or severe irritation of any particular organ; as the liver, the bile-ducts, the stomach, the kidneys, the bladder, or the uterus; or it may proceed from any one of these points as from a centre; or pain may be shifting, leaving one part and attacking another, either gradually and by a progressive movement, as in spasmodic action of the intestine from flatulent distention, or suddenly, as in some rheumatic and hysteric ailments. Pain may be constant, as in slow peritoneal disease, or glandular enlargements; or it may be periodical, as in the true or irregular pains of parturition, or the pains of dysmenorrhœa. Even the spasmodic pains of dyspepsia not unfrequently assume a regular periodical character, coming on at a particular time after meals, or shortly after the patient has retired to sleep. Pain likewise varies in its own character: it may be sharp and lancinating, or dull and oppressive. We hear patients, according to the ailment under which they labour, speak of burning pain, or gnawing pain, heavy pain, the pains of distention and of weight, sinking pains, pains accompanied with pricking sensation, or even with the sensation of hunger. Now all these, and many other modifications of painful sensations, together with the situation they occupy, the time and manner of their attack, must be carefully considered and compared in forming our diagnosis of abdominal disease.

Ninthly,—the effect of pressure with regard to pain is of great importance. It sometimes happens that abdominal pain is most decidedly relieved by pressure: this is frequently the case when the pain de-

pend upon flatulent distention of the intestines and stomach; and hence we find the patient, in such cases, lying flat upon his face, or drawing his knees forcibly towards his body. The same is the case where spasmodic action exists in the bowels independently of flatus, as in the griping pains occasioned by drastic purgatives. At other times pain is greatly increased by pressure, or, when it had not previously existed, is occasioned. This is the case in inflammatory affections of an acute kind, and more particularly while they retain their active character; and according to the part of the abdomen which is thus tender on pressure, and the degree of pressure necessary to produce the pain, do we deduce valuable diagnostic hints. When the pain is experienced or expressed on the slightest approach of the hand, we must always be on our guard, lest it should either be imaginary or should depend on some external or neuralgic tenderness; and the severity of anguish thus evinced will often rather confirm than contradict such a conclusion. The gradual increase of the expression of pain, in proportion to the pressure made by the physician, will generally be the indication of deep-seated or internal inflammation. Sometimes the pain does not immediately occur on the application of pressure, but gradually comes on after the examination has been made—the result, probably, of some spasmodic or slow inflammatory action, excited by the pressure.

I have now, Mr. President and Gentlemen, as far as the short time allotted me would permit, completed the task which I prescribed to myself at the commencement of these lectures; how imperfectly, I am well aware. I have, however, endeavoured, in the first place, to lead the minds of my hearers to the consideration of the beautiful and complex operations of those skilfully devised organs contained within the abdomen, on which our being and comfort so completely depend; then, having brought into view the various causes which are calculated, and by a wise Providence intended, to derange, and ultimately to destroy, this interesting machine, I have attempted to sketch a general outline of the various methods we possess of detecting the evils in their progress, that we may be ready to apply those means by which the same wise Providence has, in his benevolence, ordained that the skill of man may for a time avert the threatened blow; or, when this can be no longer done, may soothe the pangs and mitigate the sufferings of the dissolving body and the never-dying mind.

CONCERNING THE DURATION OF FEVERS.

From Clinical Observations at St. Bartholomew's Hospital, June 14, 1833.

BY DR. LATHAM.

WE hear nothing now about critical days. Either they have not belonged to the fevers of our own times, or they have escaped the observation of living physicians. From what I have myself seen, I never should have been led to suspect any such thing as a general law of fevers, leading them to terminate on certain specified days by a crisis.

But we do still hear not a little about fevers coming to a close on one day in preference to another. The fourteenth and the twenty-first days are said to be those on which we may most confidently look for their cessation; and of these two propitious days, popular belief is more in favour of the twenty-first. I hardly ever attended a case of fever in private practice that I was not asked, "whether it was a twenty-one day fever?" I speak now of the termination of fever independent of crisis.

It is remarkable how many opinions upon medical subjects have been admitted not only without proof, but while the evidence necessary to constitute the proof (as a little consideration might have shewn), was hardly attainable. Hence, before the admission of any opinion, it would be well first to make up our minds upon the sort of evidence required to substantiate it, and then to go in search of that evidence; for thus we should find how little warrant we have for half the conclusions we pretend to have reached.

There is an opinion that fevers have an exact duration to the very day. In order to prove its truth, our evidence must go to two points; it must establish beyond a doubt that the fever *actually did begin* on some one certain day, and *actually did cease* on some other certain day. Both terms must be proved with the same exactness. Common sense at once points out this to be the evidence required; but if it should turn out that the evidence required is not to be had—even that it does not exist in the nature of things—it would be idle to talk of a fourteen and twenty-one day fever.

Now according to my observation, there are commonly circumstances enough to fix the certainty of the first term, but seldom enough to prove the second. In the great majority of cases, a rigor, or a notable chilliness, so plainly leads the way in the order of symptoms, that the patient himself refers the beginning of his complaint to the day on which it occurred. This is the best evidence of commencing fever; and even where there is no such rigor or chilliness, the patient is often able to speak so clearly of a pain in the head, or a sickness at the stomach, accompanied by an entire change in every bodily and mental feeling, and to assign them all so distinctly to a certain day, that we cannot help regarding *that* day as the commencement of the fever.

And thus we are accustomed to find *one term* of the fever distinctly defined in the majority of cases.

In a few cases, however, there are no such circumstances, none which sufficiently mark a distinct transition from health to sickness on a certain day. The constitution is not alarmed (as it were) by any sudden inversion of its healthy feelings and functions, but the symptoms steal upon the patient by little and little, and gradually involve him in a fever, while he is unable to say on what particular day he began to be ill.

But with whatever certainty we may assign the beginning of fever to a particular day in any case, we obtain no exact measure of its duration, unless we can assign its termination to a particular day with the same certainty.

Fever can only be punctually known to terminate on a particular day by some marked change in the symptoms—by circumstances shewing the transition from disease to health at the end of the fever, as distinctly as the transition from health to disease was marked at its commencement.

Such a change at the end of fever, it has occurred to me to witness in very few cases; and then the circumstances denoting the change have been those which constitute a crisis.

A clean and moist tongue, a reduced pulse, abated thirst, and healthy sensations of body and mind, all arising in the course of a few hours, cannot be mistaken, and they fix the date of convalescence to a certainty. But all these notable changes are not apt to occur thus quickly and simultaneously, unless

led on by the spontaneous exuberance of some natural secretion, especially that of the skin.

Ordinarily they occur after a different manner. The tongue becomes more and more clean and moist, and a day arrives when it is absolutely so. But this may not happen until, judging from the pulse and other symptoms, we may have already considered the patient convalescent. So, too, the pulse becomes less and less frequent, and a day arrives when it reaches the numerical standard of health; but this may not be until a clean tongue and an improved appetite have proclaimed the patient several days advanced towards health.

If physicians had agreed to regard any single symptom, or any two or three symptoms, as pathognomonic of fever, then, as soon as these ceased, they might safely pronounce that the fever was gone. But this is not the case. It is from a great variety of particulars that we make up our mind upon the existence of fever, being unable to assign to each symptom the exact weight which it should have in fixing the nature of the disease: and thus, wherever fever has existed, it is only from the like variety that we can learn when it has ceased; not knowing that the disappearance of this or that symptom necessarily carries along with it the disease itself.

But although, except in the event of a crisis, fevers may not furnish data sufficient to fix their termination punctually to *one* day, do they not furnish enough to comprehend it within the space of two or three days? And thus, if they do not come to their close *exactly* on the fourteenth or twenty-first day, do they not, nevertheless, end sometime about one or other of these days—that is, towards the conclusion of the second or third week? We shall see.

I have endeavoured to note the beginning and the end of fever in 309 cases. By noting the beginning, I mean *the very day of* its commencement; by noting the end, although I have specified a certain day, I do not wish to imply more than *that some time about that* day the patient began to get well.

The data upon which we rest our belief that the disease is past and health returning, are, that the skin has become cool; the tongue is of an uniform moisture and colour, though it may not yet

be entirely clean; the pulse is much reduced in frequency, though it may not yet have come to the standard of health; that the appetite for *solid* food has returned; that the functions of particular organs which have suffered harm or hindrance are restored; and, above all, that the patient has again become conscious of natural and healthy sensations. It has been from data of this sort that, in drawing up a short tabular view for the purpose of illustrating our present subject, I have ventured to mark the day *somewhere about which* each of nearly three hundred cases of fever terminated. And in this table their termination (I am persuaded) is assigned to a particular day with as much accuracy as the nature of the subject will admit. At all events, be the accuracy what it may, it belongs in the same degree to the numbers of one day as to those of another.

Of 309 cases of fever, there were twelve of which the duration could not be satisfactorily calculated. The remaining 297 cases terminated upon the days specified in this table.

Days of the Fever.	Number of Cases ending on each day.	Days of the Fever.	Number of Cases ending on each day.
5	2	33	8
6	3	34	6
8	3	35	5
9	6	36	1
10	3	38	3
11	12	39	5
12	13	40	8
13	12	41	3
14	8	42	4
15	9	43	2
16	14	44	3
17	12	45	1
18	16	46	4
19	8	47	1
20	9	48	1
21	8	49	8
22	7	50	1
23	9	51	1
24	10	53	2
25	6	55	2
26	4	56	1
27	7	57	2
28	8	59	1
29	4	60	1
30	11	62	1
31	11	65	1
32	6		

Taking, then, the numbers exactly as they are represented in the table, it would appear that fewer cases terminated on the 14th and 21st day than on several days both prior and posterior to each. Out of two hundred and ninety-seven cases, eight only terminated on the 14th, and eight on the 21st.

For a fever to end before the 10th, or to be protracted beyond the 31st day, is unexpected and unusual. Thus a range of twenty-two days embraces the period within which the majority of cases come to their close; and, within this range, the table shews that there are twelve days (above half) more favourable to the termination of fever than either the 14th or 21st. Two equally favourable, and six only less so.

But let us allow a still larger latitude in seeking to know whether fevers are apt to come to their close *some time about* the 14th or 21st day. Let us take a range of three days, by joining each of these with the day immediately before and the day immediately after it; and then, adding together the number of cases which ended on the 13th, 14th, and 15th, and on the 20th, 21st, and 22d, let us see what proportion the sum bears to the number ending on any other three days taken consecutively.

Thus on the 13th, 14th, and 15th days, taken together, twenty-nine cases terminated; and on the 20th, 21st, and 22d, taken together, twenty-four cases terminated. These are our standards of comparison. But on the three days preceding our first standard of comparison, viz. the 10th, 11th, and 12th, twenty-eight cases terminated; and on the three days succeeding it, viz. the 16th, 17th, and 18th, forty-two cases. Again, on the three days preceding our second standard of comparison, viz. the 17th, 18th, and 19th, thirty-six cases terminated; and on the three days succeeding it, viz. the 23d, 24th, and 25th, twenty-five cases.

Finally, then, from the event of these two hundred and ninety-seven cases, no proof can be derived that there is any law of fevers inclining them to terminate upon one particular day more than another, or even *some time about* a particular day, whether it be the 14th or 21st, or any other day.

I hope you do not think me presumptuous for thus calling in question a much-received opinion respecting the duration of fevers; and venturing to

suspect that medical men in general have not been quite aware how much evidence is required to substantiate its truth, and have thus been content to let it pass.

The result of my experience points to the conclusion, that the duration of fevers is indefinite. But the cases which furnish the materials of my induction occurred between 1826 and 1832 at St. Bartholomew's Hospital. So that mine is the experience of a particular time and a particular place; and I do not claim for it more than it is worth.

There are varieties found in many diseases which bear the same name, and in none more than in fevers. And although all fevers, wheresoever they are found, may have something in common which respects their essence, yet the fevers of different times and places admit of so great varieties that no physician, drawing from his own experience alone, (however great it may be) must venture to speak of what fever is *absolutely*.

From the forms of fever which passed under my own observation at St. Bartholomew's Hospital between 1826 and 1832, I cannot fix upon any as a specimen of the fever of all places; not of the fever which occurred at the same time in Europe, or even in other parts of England. But perhaps I may safely rely upon my own experience of what occurred at our largest hospital during this period for furnishing me with just examples of the fever simultaneously prevalent in London, and may be allowed confidently to affirm that, during the last seven years, no such thing has occurred in London as a fourteen or twenty day fever, or a fever of any definite duration whatever.

But is it not among the characteristics of certain epidemics that they have a definite duration? Not to recede from the particulars of my own observation, I should say that at one time the prevalent fever may be generally long; at another it may be generally short. This is all I know. But, upon the whole, I should always prefer to calculate the probable duration of every particular case by its own circumstances, by things contained in itself, rather than according to any supposed law of the epidemic.

ON ŒSOPHAGEAL VOMITING.

To the Editor of the Medical Gazette.

SIR,

I HAVE recently had an opportunity of watching, with Mr. Brodie, the effort to swallow, and the effort to vomit, in a patient with total obstruction at the cardia.

The effort to swallow was not to be distinguished from that in health; nor could the patient detect any difference, until the œsophagus being completely filled, the fluid ceased to descend beyond the pharynx, and flowed out of the mouth.

The effort to vomit was also perfectly similar to that which takes place in health: the larynx was closed, an effort of expiration was forcibly made, and the fluids in the œsophagus were expelled as in ordinary vomiting.

The stomach-tube was introduced repeatedly. Whenever it reached the cardia, and so extended the œsophagus, an effort to vomit uniformly took place, as in the experiments of Legallois; at the same moment the fluids contained in the œsophagus were forcibly expelled through the tube.

The whole of the phenomena in this case afforded an interesting confirmation of the views I had published on the Mechanism of the Act of Vomiting, which were copied in the Medical Gazette for April 2, 1828.

In ordinary vomiting, the abdomen and thorax become as one cavity, the intervening diaphragm floating perfectly loose and inert between them, whilst the cavity of the stomach and of the œsophagus become equally one, by the free opening of the cardia; an *effort of expiration* then takes place, and the stomach is evacuated through the œsophagus.

Your obedient servant,
MARSHALL HALL.

Manchester-Square, June 22, 1833.

ON THE FUNCTIONS OF THE LIVER AND USES OF THE BILE.

To the Editor of the Medical Gazette.

SIR,

AT the request of many persons who were not present at the meeting of the

Royal Society in which a paper of mine was read, having for its subject the Functions of the Liver and the Uses of the Bile, I have consented to make it public in the present condensed form.

It is possible that, to some, the investigations contained in the present communication may appear incomplete, or inconclusive: should this be the case, may I beg them to suspend their judgment until they shall be in possession of the second and concluding portion of the investigation.

I am, sir,

Very faithfully yours,

BENJAMIN PHILLIPS.

17, Wimpole-Street,
Cavendish-Square, June 1, 1833.

The object of the paper submitted to the consideration of the Society, was to prove that the generally-received opinions upon the functions of the liver are incorrect.

To establish the erroneous character of these opinions, the following propositions were sought to be proved:—

1st. That the bile is a fluid, the principles of which exist in the blood before it arrives in the liver.

2dly. That this fluid may, under certain circumstances, be secreted from arterial as well as from venous blood.

3dly. That good chyle may be formed in the absence of bile.

4thly. That bile is required, principally if not altogether, for the purpose of exercising upon the intestinal tube a stimulus, by which it is excited to evacuate the excrementitious matter which it may contain.

All glandular organs are supplied with a quantity of blood quite disproportioned to their bulk, and we are obliged to come to the conclusion that the blood is not sent to them simply for the purpose of affording them nutrition, but for the purpose of being subjected to some process by which certain materials which it contains are separated from the mass.

Whether or not the materials of all the secretions exist in the blood before it arrives at the organ in which they are separated, is as yet undetermined; though the experiments of Chevreul and others strongly tend to the conclusion that they do. In any experiments which may be made with a view to determine this question, much difficulty will be experienced; for, with the ex-

ception of certain of the principles of the bile and of the urine, the materials of secreted fluids may be found in the serum of blood taken from any portion of the system. The facts cited by Stahl, Lacaze, and Borden, and the reasoning which fairly arises out of them, strongly favour the conclusion, that all the materials furnished by the different secretory organs pre-exist in the blood, and that the secretory organs do no more than remove these principles from the blood. Whether this separation be effected through the agency of the peculiarly-modified sensibilities of the several organs, or through that of their particular organization, is not material in this place.

It is true, as I have already stated, that by direct chemical experiment we have not yet succeeded in demonstrating in the blood of a healthy subject the materials of all the secretions. It is equally true, that if from any cause a secretion be suppressed, we are enabled to detect its principles in the blood. In the healthy state, we have not been able to demonstrate in the blood the principles of the biliary or urinary secretions; but if, in consequence of disease, or of experiment made for the purpose, these secretions become suppressed, then we experience no difficulty in demonstrating in the blood the existence of the biliary or urinary secretion.

Certain experiments were made by MM. Prevost and Dumas, for the purpose of determining this question in as far as regarded the secretion of urine.

These gentlemen removed from dogs the two kidneys. Before they did so, they made a minute examination, for the purpose of ascertaining whether they could detect urea in their blood, but without success. In a few hours after the performance of the operation, the blood was examined by a process precisely similar to that which had been previously employed, and its existence was immediately made evident. The truth of these experiments has been confirmed by the experiments of MM. Vaugelin, Segalas, and Magendie. I have varied the experiments, by placing a ligature around the whole of the renal vessels, and allowing them to remain in the abdominal cavity, instead of extirpating them; and my conclusions are entirely similar to those I have already stated.

Many cases are detailed in which the

urine has been separated from the blood by other organs besides the kidneys. These experiments and those cases clearly establish, as I submit, that the kidneys are not, as is generally thought, the generating organs of the urea, and that they simply separate it from the mass of blood in which it pre-exists.

If these principles exist in the blood, it becomes an object of interest to ascertain whether they are generated in it or brought into it; but as this question is the subject of another paper, now before the Royal Society, but not yet read, I cannot further enter into its consideration at present.

When the biliary ducts are free, and when no bilious fluid occurs in them—that is, when a suppression of the secretion occurs—we find that the yellow and the bitter principles of the bile may be demonstrated in the blood, the urine, and many of the other secretions and exhalations.

When, from disease, or the application of a ligature, the vena portæ becomes obliterated, jaundice is usually produced. I shall terminate the evidence by which I propose to shew that the principles of the biliary secretion exists in the blood before it arrives at the particular organ in which the separation is to be effected, by stating that the Royal Society are in possession of the details of three cases in which the vena portæ and the hepatic artery were secured, and yet jaundice was produced; no secretion of bile occurred in the liver, and the urine was intensely yellow.

If the foregoing observations be correct—if the analogy I draw from the secretion of urine be not strained—if, when the secretion of bile no longer occurs in the liver, many of its principles may be demonstrated in the blood and in many of the secretions—if, when the tissue of the liver be entirely broken down, similar phenomena be produced—and if the experiments of which I have spoken be correct (and that the whole of these facts are unimpeachable, I feel the strongest conviction)—then I am undeniably justified in maintaining the truth of my first position, “that the principles of the bile exist in the blood before it arrives at the particular organ in which the secretion is to be effected.”

The second point I proposed to establish was, that bile may be separated from arterial as well as venous blood. In the Clinique Médicale of Andral,

and in two articles contained in *Les Archives Générales de Médecine*, tom. ii. written by Bouillaud, may be found the details of several cases which had occurred at La Charité, in Paris, in which the vena portæ had become obliterated, either in consequence of compression produced by tumors developed in the abdominal cavity, or by the development of inflammation in its parietes; and in which the secretion of bile appeared unchanged. In other works, to which I shall immediately refer, we find detailed four well authenticated cases in which the vena portæ, instead of passing as usual into the liver, terminated in the vena cava abdominalis, and the blood was carried directly to the heart; and in three of them jaundice occurred. In each of them, the only vessel of any importance which entered the liver was the hepatic artery. In all, the secretion of bile was performed in sufficient quantity for the purposes of the economy. Of these, one is described by Lieutaud (*Hist. Anat. Méd.* tom. i. p. 190); a second by Huber (*Obs. Anat.* p. 34); a third by Abernethy (*Phil. Trans.* 1793, p. 59 to 63); a fourth by Lawrence (*Med. Chir. Trans.* vol. v. p. 174.)

The absence of the system of the vena portæ in invertebrate animals, although the secretion of bile exists, and in large quantity, I also rely on as a strong corroboration of the opinion I have stated.

The last fact to which I shall allude in support of this position, is the issue of three experiments, the details of which are in the possession of the Royal Society, in which the trunk of the vena portæ was tied before it enters the liver, and two in which the hepatic artery was tied. In each case the secretion of bile continued; the quantity was smaller than before the application of the ligature.

Such are the facts upon which I conceive I am entirely warranted in founding my conviction “that bile may be separated from arterial as well as venous blood.”

The third point I propose to prove, is that good chyle may be formed in the absence of bile.

In Andral's Clinique Médicale, *Maladies de l'Abdomen*, we may find detailed at length three or four cases in which the ductus communis was obliterated, either in consequence of compres-

sion produced by a tumor or other body, or by the development of inflammation within its parietes.

In these cases chylication went on as usual.

In some molluscous animals, only a small portion of the bile is emptied into the smaller intestine, and that into its inferior portion. The remainder passes, through particular excretory tubes, either into the cæcum or still nearer to the anus, and passes off as excrementitious matter, without undergoing any change.

The Royal Society are in possession of the details of several cases in which the ductus communis was tied, in which no bile could get into the intestinal tube, and yet in which chyle of good quality, possessing no obvious difference from that taken under ordinary circumstances, either in quantity or quality, was found in the thoracic duct.

To this evidence I may add that which is furnished by the results of the experiments made by Tiedemann, and Gmelin, and Lassaigne; which, as I submit, confirm in the most complete manner, not only the truth of my experiments, but the justice of the opinion I have expressed—"that good chyle may be formed in the absence of bile."

I have now occupied much time in offering evidence to prove that the opinions at present held with regard to the functions of the liver, and the uses of the bile, are incorrect; and I am now clearly called upon to state what opinions I propose to substitute in their place.

That the use of the liver is to separate from the blood a principle called bile, is, I trust, fully established; as also that this principle already exists in the blood; and that this secretion is made for the purpose of attaining two objects, I trust to prove satisfactorily.

If good chyle may be formed in the absence of bile, as is, I submit, fully proved, the conclusion is, I believe, irresistible—that the secretion of bile is formed for some other purpose than assisting in the formation of that substance.

It has been shewn in almost every observation and experiment which I have detailed, that in the absence of bile the alvine evacuations became extremely infrequent; that they attained great consistency, and that their expulsion was consequently attended by pain and

inconvenience; and that, if the bile again flow in its natural channel, these symptoms rapidly disappear. It has also been shewn by Tiedemann and Gmelin, that in the cæcum, and even in the rectum, we may demonstrate the principal materials of the bile, about to pass off as excrementitious matter.

I now feel that if actual demonstration were possible, it would be little, if at all, more conclusive than the reasoning which must follow these facts; it must impel us to the conviction that one, if not the only, great function of the biliary secretion, is to produce a fluid which, by its stimulating quality, shall excite the intestinal tube to contract upon and expel its contents.

In the function performed by the liver another great object is attained: certain principles are removed from the blood which, if permitted to remain in the general mass of the blood, would exercise on the animal economy a deleterious influence.

Look to another circumstance: if the ductus communis be tied, or if its obliteration be effected by other means, the separation of bile is effected by the other glandular organs—the kidneys, the salivary glands, &c. Here it can have no reference to digestion, and must be an excrementitious fluid. Again, in those molluscous animals, as some of the limaces, the aplysia, &c. in which the bile is emptied in the immediate neighbourhood of the anus, it can only be an excrement.

If these deductions be correct, animals in which icterus exists do not die from a want of a sufficient supply of properly elaborated chyle. From what then do they die? Simply, as I believe, from the deleterious action exercised upon the economy by the presence of bile in the general circulating system.

If we inject bile into the stomach of a dog, we produce immediate vomiting, succeeded by diarrhoea; if we inject it into the intestinal tube per anum, we produce immediate evacuations.

It is evident, therefore, that the bile has the power of stimulating the intestinal tube to excited action.

I have now shewn, that in the absence of bile good chyle may be formed; that without the presence of bile, the intestinal tube ceases to act with that energy necessary to the expulsion of its contents; that when the intestines are in

this inactive state, they may be stimulated to healthy action by the presence of bile.

In conclusion, it may be necessary that I should shew that the presence of bile in the circulating system will produce deleterious effects, and even destroy life. If two drachms of bile be injected into the femoral vein of an ordinary-sized dog, in a few hours he becomes jaundiced, his mouth becomes dry, he vomits, becomes comatose, and dies. If the quantity be lessened, the effects are less marked. In either case the urine and other secretions become tinged with bile.

Here, then, I terminate the evidence in support of the opinions I have expressed. Any links which may here appear wanting to complete the chain of investigation necessary to the entire elucidation of this very important question in physiology, will, I trust, be found in my second paper on this subject.

ON THE TEETH—AS A SOURCE OF HEALTH OR DISEASE.

To the Editor of the Medical Gazette.

SIR,

HAVING been frequently asked to state whether I have any peculiar views on the diseases incident to the formation, growth, and decay of the teeth, and having occasionally been addressed in terms semi-douces, semi-ameres, upon the claims I may have to some share of originality in the trains of inquiry in which I have for some time been engaged, I take the liberty of requesting your insertion of the following propositions. Allow me only to premise, that if all other inquirers cannot at once perceive the dependence which exists between the phenomena involved, an accusation of a mere fanciful connexion between them is no reply to the arguments which it has taken me years to store up, and which will yet require some patience as well as industry to arrange for the public. I propose that,

1st, The normal growth of the infant cannot proceed without a normal arrangement and development of its organs of suction and mastication.

2d, Anormal arrangements and developments of the teeth constantly irregulate the health.

3d, The development of the second

dentition may be accompanied by the same trains of disordered health as that of the former dentition.

4th, The errors of health arise, during the progress of dentition, *chiefly* from injuries to the nerves of the jaws and of the dental matrices; the trains of development of the teeth and of the jaws proceeding without a due consent between them.

5th, The diseases which are incident to anormal conditions of growth of the teeth and jaws inflict their penalties upon various organs, sometimes producing lesions more or less extensive. Among these diseases may be enumerated fevers (particularly infantile remittent fever, and the remittent fever of childhood); spasms of certain muscles (wry neck); spasmodic croup; anormal contractions in the course of the alimentary canal (intus-susception); some tetanic affections; some hysteric affections; some uterine disorders; neuralgia; (tic and nervous pains in the side in females, commonly attributed to hysteria;) chorea; epilepsy; catalepsy; oblivious states of mind; sick headaches; nervousness; *stammering*; *tardy access of the power of speech in children*; some inflammations in strumous subjects, particularly of the hip and knee-joint, and of the peritoneum and mesentery; diseased lymphatic glands; inflammations of the tonsils and of the trachea (inflammatory croup?); diarrhoea, with inflammation of the mucous surfaces and muciparous glands of the intestines (atrophia ablaetatorum of Dr. Cheyne,) a disease occurring as well during second dentition, in childhood, and adult age, as in infancy, accompanied often by prolonged typhoid fever, and terminating in death, if unrelieved by the gum lancet, or by the favourable progress of development: Phthisis and anasarca sometimes supervene to this disease, when it results from anormal dentition; hydrocephalus acutus; strabismus; amaurotic blindness; deafness; coma; apoplexy and hemiplegia; a wide range of cutaneous diseases, particularly those affecting the head and neck (*Porrigio larvalis*, *P. favosa*, and especially *P. scutellata*, molluscous excrescences.)

That these propositions are calculated to raise a smile on the countenances of many who have arrived at a certain time of life, I am quite prepared to believe;—that the profession contains many who would rather smile than

examine, I know too well. When my avocations permit, I shall offer you, sir, some of the facts upon which my views rest. In the meantime, of those who pursue our profession with the liberal feelings of scientific gentlemen, I must beg that John Hunter's few last pages on Dentition may be consulted, and that Bichat's hints on the divers sympathies of the Teeth, contained in his *Anatomie Générale*, part ii. art. 5, may be referred to. My subject is there begun; and if the facts which I have adduced in my lectures, and which I hope soon to publish in another form, do not lead to further inquiry, they will merit the neglect with which they will be treated.—I remain, sir,

Your obedient servant,

JOHN ASHBURNER.

5, Wimpole-Street, June 8, 1833.

ACCOUNT OF THE COVENTRY SELF-SUPPORTING DISPENSARY.

To the Editor of the Medical Gazette.

SIR,

IN addition to the valuable remarks contained in the *Gazette**, several publications from the pens of distinguished practitioners have issued from the press, explaining the principles and recommending the adoption of self-supporting dispensaries; but I am not aware that any details of the practical operation of these institutions have been hitherto submitted to the profession.

As a dispensary on that principle has existed and prospered in this city during the last two years, it cannot be thought premature to regard it as a successful exemplification of the views so long and zealously advocated by Mr. Smith of Southam; and I venture to presume that such remarks and extracts from the two printed annual reports as illustrate the operation and extent of our institution, will not be considered uninteresting. But before proceeding with these remarks, I shall advert for a moment to the motives which induced the adoption of it in Coventry, and briefly explain the circumstances and resources of our operative population.

The establishment of a self-supporting dispensary was determined on at a

public meeting held in this city more than two years ago, and chiefly on three grounds: first, because it was deemed a duty to encourage the poor to supply their own wants by their own means as far as possible; secondly, because sufficient funds to support a charitable dispensary on a scale commensurate with the wants of the population, could not be relied on; and, 3dly, because it was considered a matter of justice to recognize and adopt the principle of remuneration to the medical attendants on dispensary patients. The experiment instituted here has conclusively established the practicability and efficiency of such an institution, and will be found to afford a striking and satisfactory contrast to the excessive and (as it would appear from our experience) the superfluous aid supplied by the usual eleemosynary dispensaries*.

In order to shew the amount of relief afforded by our institution in comparison with the population, and at the same time to indicate the necessity for a public provision for the sick poor of the city, it is necessary to state that the population of Coventry, according to the last census, rather exceeded 27,000. The poor-rates (which supply a just criterion of the average condition and resources of the labouring community in any locality) have certainly not been lower, but probably a good deal higher than in most other large towns in England. The staple trade of the place has for years past been much depressed, nor does any well-informed person anti-

* "Very few, I think, (says Dr. Jeffreys, of Liverpool) have any idea of the extent of gratuitous (of late called honorary) services to which physicians and surgeons gladly submit themselves in this town. Last year, I believe, out of a population of about 160,000 souls, one-third of these received gratuitous medical and surgical assistance from the infirmary and dispensary, exclusive of patients in the fever hospital, work-house, and other minor charities."—*Midland Medical and Surgical Reporter*, XIV. p. 120.

In the eloquent pamphlet of Dr. J. P. Kay, (on the moral and physical condition of the working classes employed in the cotton manufacture in Manchester, it is stated (page 68) that "without including the Lock Hospital and the Eye Institution," during the year preceding July 1831, 27,804 patients were relieved by the medical charities of that town. At page 69, Dr. Kay further remarks that, "assuming the population of Manchester and the environs to be 230,000, more than one-half of its inhabitants are either so destitute or so degraded as to require the assistance of public charity in bringing their offspring into the world." And it is a reasonable presumption that a statistical inquiry into the subject would exhibit an equally lavish administration of medical charity in other populous localities in numerous parts of the kingdom.

* See number for September 22, 1832.

cipate a higher rate of remuneration to the artizan than he has received during the period alluded to.

It would not be anticipated that, in a manufacturing population of such extent and so circumstanced, with the exception of the usual pauper establishment, no institution existed—not even in the form of sick clubs or otherwise, for supplying medical aid to the labouring community of the city. It may be fairly presumed, therefore, that Coventry presented a very suitable opportunity for the introduction of the self-supporting system of dispensaries.

Although the adoption of a dispensary on this principle was resolved on at a public meeting held in March 1831, owing to unavoidable delays it was not opened for the admission of members until the 18th of July following. The first annual report thus describes the admissions during the year:—

“The admissions on the 18th July, 1831, were 50		
The number in August amount-	ed to	150
... September		390
... October		830
... November		1150
... December		1270
... January 1832		1540
... February		1930
... March		2280.”

The committee, for reasons detailed in the first annual report, proposed to limit the number of members to 2500. Immediately after the publication of the report, the admissions amounted to that number, and as vacancies have occurred they have been from time to time filled up, but the limitation recommended by the committee is still adhered to. Indeed the funds of the institution will not allow of any considerable increase in the number; nor, if they would, is such increase desirable, as there is good reason to think, that, with the exception of paupers, from 2500 to 3000 would comprise all the inhabitants of this city who are not in circumstances to meet the charges for medical attendance in the usual way.

The first annual report proceeds to state that “the general description of persons admitted as free members may be comprised in three classes. The first, and by far the most numerous class, are those who have been without any medical aid whatever, the lamentable conse-

quences of which have in many cases been painfully evident to the surgeons of the establishment; secondly, those who have usually sought gratuitous advice from the physicians and surgeons, and have procured their medicines from druggists; and, thirdly, those whose situations in life rendered the payment for medical advice very precarious.”

The following statement will exhibit the number of patients treated during the two years respectively:—

	1831-32	1832-33
Cured	1189	2428
Relieved	101	99
Dead	19	30
Under treatment	186	125
Midwifery cases	10	55
Number of patients treated	1505	2437

The funds of the establishment are derived from two sources; first, from the weekly payments of the working classes who are called free members*; and, secondly, from honorary or charitable subscriptions and donations, the contributors to the latter fund being the governors or directors of the institution. All the expenses of the institution, with the exception of the charge for drugs, are defrayed by the honorary fund. The drugs alone are paid for by the free members' fund, and the surplus (amounting in 1831-32 to 80*l.* 17*s.* 6*d.*; and in 1832-33 to 263*l.* 1*s.* 5*d.*) is divided between the surgeons of the dispensary.

[The author here inserts a financial abstract from the books of the institution, for which we regret that our limits will not allow us room.]

From this statement it appears that the charge on the honorary fund, comprising the salaries of the dispenser and clerk, rent, levies, and taxes, together with occasional donations of broth and loans of linen: (distributed to the patients “in cases of severe affliction” by a ladies' committee, on the suggestion

* The following rule regulates the payments of the free members. “Every free member above twelve years of age shall pay one penny, and under that age one halfpenny per week, except in a family consisting of more than two children, when one penny shall be considered sufficient for all under twelve years of age. Servants shall pay five shillings a year, and in not less than half-yearly payments. The payments of every free member shall be made in advance.”

of the surgeons) in fact, every expense of the dispensary, exclusive of drugs, does not exceed 140*l.* per annum. And this is the whole charge on the *charity* of the wealthier inhabitants for the support of an institution which has shewn itself able to supply the most prompt, diligent, and efficient medical aid to all that portion of this large manufacturing population, whose circumstances render them unable to defray the expense of medical attendance in the usual manner. It is almost superfluous to say that the sum is considerably smaller than is usually expended on eleemosynary dispensaries in a population of equal extent.

But independently of the financial facilities of the system, it possesses the higher attribute of moral excellence in the opportunity and encouragement it affords to the poor to rely on their own resources rather than on the inexpedient, (and as this institution proves) the unnecessary, and therefore mischievous charity of others. It has the farther recommendation of justice to the profession in recognizing the principle of remuneration for the services of the medical attendant. The proverbially active benevolence of medical practitioners has led them to sacrifice much valuable time on the patients of eleemosynary institutions, but it admits of serious doubts whether, in the instance of dispensaries*, they have duly considered the full consequences of their excellent institutions; whether they have sufficiently regarded the just claims of junior practitioners, or the injurious tendency of dispensing systematic charity to persons who are not necessarily dependent upon it. The truth appears to be that the assistance

now rendered by eleemosynary dispensaries is in a considerable degree unnecessary, and that that department of practice ought to devolve on the properly qualified junior practitioners in a town. The remuneration, according to the arrangements of a self-supporting dispensary, though unequal to the deserts of the medical practitioner, exceeds the average payments from benefit societies or sick clubs, and it is presumed would be found more satisfactory than the precarious recompense derived from that class of persons where no associations exist to aid their honest endeavours. Such remuneration would be an honourable and useful resource to the young practitioner until his time became more valuable by the acquisition of private practice, to which these institutions would be, so to speak, a stepping stone; an appointment to a self-supporting dispensary, affording him the great advantage of an early opportunity of evincing his professional talents and acquirements, and thus establishing the soundest claim to public patronage. In his original plan Mr. Smith proposed that the practice of self-supporting dispensaries should be open to all the general practitioners in a town; but our experience in this city would induce us to suggest that the duties and remuneration should be concentrated within narrower limits.

Objections to the title of *Self-supporting* Dispensaries have been started, on the ground that they are not independent of charitable aid*. Strictly speaking, the objection is a valid one, but considerable advantages to all the parties concerned arise out of the assistance derived from the "honorary" contributions; and considering the comparatively small extent of assistance received, the infringement of principle is not considerable. Were the payments of the free members made sufficiently high to meet the whole expenses of the establishment, the operation of the Dispensary would be confined to artisans receiving a high rate of wages, to the exclusion of those who most need the assistance of such an institution, and without at all increasing the remunera-

* Hospitals will always remain, in a considerable degree at least, charitable institutions. At Hamburg, however, patients are admitted into the great hospital who contribute towards the expenses, and are called "*boarder-patients*." Dr. Traill says, in his account of that hospital, "there are many rooms, of different sizes, occupied by *boarder-patients*." And he observes, "the idea of admitting such patients appears worthy of notice. It encourages feelings of independence in the poor who are above accepting assistance as an eleemosynary boon, and yet can ill afford the expense of a protracted illness. Many persons are received as boarders in the Hamburg hospital of the class that with us are gratuitously relieved in our dispensaries and infirmaries, a circumstance unavoidable where there is no medium between an expensive treatment in private, and public charitable relief; except, indeed, where the poor have associated themselves into friendly societies and sick clubs, institutions deserving of every encouragement."—*North of England Medical and Surgical Journal*, p. 423.

* The founders of the Coventry Self-supporting Dispensary, conscious of such an objection, denominated their institution "the Coventry Benevolent Dispensary." The epithet "Self-supporting," appears, however, to be most appropriate, as indicating the characteristic principle of the institution.

tion to the medical attendant. But a still more important consideration is, that the contributors to the honorary fund become, in virtue of their donations or subscriptions, the governors of the institution, and have the whole management and direction of the establishment. This is a desideratum of the first importance, as furnishing the best security for the impartial administration of the affairs of the institution. Judging from what is frequently observed in benefit societies, in which the control and direction is confided to the ordinary members, it is exceedingly probable that such inconveniences and impediments would arise, were the management of the affairs entrusted to the free members of the Dispensary, as would be speedily fatal to the institution. A committee of management formed from the honorary subscribers, ensures protection to the just interests of the profession, by confining the admission to proper persons; as the eligibility of every free member for admission is determined by such committee, which consists of gentlemen whose local information and general knowledge of the circumstances of the labouring classes qualify them to form a correct opinion, without having recourse to any special inquiries or proceedings, which the candidates for admission might deem inquisitorial.

Under the surveillance of a committee thus constituted, the Coventry Dispensary has flourished during the last two years beyond the most sanguine expectations of its founders. The circumstances of the place, it is true, were exceedingly suitable to the introduction of the Dispensary, but there must be a natural fitness in the system itself to have led to such marked success.

Your very obedient servant,
R. ARROWSMITH, M.D.

Coventry, May 31, 1833.

THE APPRENTICESHIP SYSTEM.

To the Editor of the Medical Gazette.

SIR,

As the public mind is at present much agitated by the question of medical education, I must beg a place in your journal, as I believe in the present, as well as other questions of interest, you

are desirous of keeping in view the old maxim — “Audi alteram partem.”

The point, however, I have in view is only one part of the question at issue, for I do not wish to inquire into the merits or demerits, of the good or evil, likely to result from the admission of Scotch apothecaries into England, but to inquire, whether or not the Society of Apothecaries of London have made the best use of that Act, which, “after some opposition, passed on the third reading by a single vote, at the moment the house was breaking up for the session,” and which came into operation on the 1st of August, 1815.

There is no person, I think, who can reasonably deny that the improvement of medical science has of late years been very great, and this may be accounted for by the impartiality with which the examinations of candidates for certificates to practise as apothecaries have been conducted. So far, so good; and the subject might here be dismissed, did not another question arise out of it. The question I allude to is this, — do, or do not, the Court of Examiners act honourably in refusing an examination to a candidate who is unable to show an indenture of apprenticeship for five years to an apothecary, though in every other respect he may be fully competent to undergo such examination? It must be allowed that the art of compounding and dispensing medicines is an essential qualification for an apothecary; but is, or is not, five years a longer term than is required to learn this? or is not a five or seven years’ apprenticeship to a respectable chemist and druggist a guarantee for this part of the question? And to push the question closer home, it may be asked, why, if this is not sufficient, does it come to pass, that we every day hear the apothecary railing at the druggist for robbing him of the best and most profitable part of his business — that of dispensing medicines and prescribing behind the counter? and surely if he does this, he must do it successfully, or he would bring obloquy on himself; and if he does it successfully, is he not able at least to teach his apprentice? But here, again, the wide question of the real or supposed ignorance of the druggist presents itself to our notice, and daily experience fully convinces every candid inquirer, that the profession of chemist and druggist is more or less in every town assumed

by the most ignorant and unlettered part of the community. But are we to condemn the many for the few? Candour will say, certainly not. But, to take another view of the case, in how many families are there to be found two sons of equal abilities, who have enjoyed the same advantages at the same or equally-rated academies, the one of which has been regularly apprenticed to a surgeon-apothecary, the other, owing to the inability of his parents to support the expense of his education, has been prevented following his inclinations: but allowing that in the course of a few years his resources are augmented, and this young man is at leisure to turn his attention to the study of medicine, is he, or is he not, able to learn as much in a year as his brother has done in five? This is, I think, a question which will not find a ready solution. However, he attends the lectures required by the Court of Examiners, and applies at the Hall for an examination; and the beadle is authorized to tell him, with all the gravity of a judge, that his request cannot be granted. But why? why because they wish to prevent unqualified, or rather unexamined persons, from practising; and so, not because he is unable to pass this said examination with credit to himself, but because he cannot shew that some apothecary has had a fee of indenture, he must go back, and at the age of from 21 to 25 years, bind himself five years to an apothecary to learn that which he has already learnt by incessant and wasting study: and though it may be said that such cases are an exception to the general order of things, and that few are in the situation I have described, yet I may venture to assert that although these cases are exceptions, they not unfrequently occur under the same or similar circumstances; for the same train of reasoning will hold good with regard to the case of a young man who may have suffered through the caprice of a guardian, or the son of a gentleman resident abroad, &c. &c.; and I may beg leave to add, that though they are individual cases, they are numerous, and not only attended with extreme hardship on the part of the sufferers, but with barefaced injustice on the part of the examiners; for though they may argue that laws were never made to meet the exigencies of the few, but for the good

of the many, yet I would ask them if this is the case, and if in one point they are so strenuous in the prevention of abuse, why are they not so in another? And in order to convey my meaning here, I would ask, in the first place, have two-thirds of those candidates for examination who are able to shew an indenture of apprenticeship for five years to an apothecary, served that time in full? In and near London, more particularly, every body knows the five, six, or seven years' indentures to be a mere form: it is true they may be bound for one of these numbers of years, but at the first, owing to the master not having sufficient practice to employ him, the hopeful youth is sent back to play away a year or two at school; he then, for three years at the most, is supposed to turn his attention to the making up and dispensing medicines; and the last two years are supposed to be spent at the hospitals; but owing to the present system, half this time (and the summer months too) are devoted to the pleasing task of visiting country friends, shooting, fishing, cricket-playing, &c.

Secondly, it is an undoubted truth that many young men who have not been apprenticed at all, or who have been improperly apprenticed, have, owing to being refused an examination without it, got a nominal indenture, setting forth that the bearer has *regularly* and *faithfully* served the term of five years, whilst he has been four or five times to Greenland or Davis' Straits in a whale ship, or once or twice to the South Seas on the same errand, or to the East or West Indies in the capacity of "Doctor!" to pass away the time. How could he, or could he not, have passed his examination before he went? if he could, what occasion for this *much-needed* instrument; if he could not, would it not have been far better, on the part of the Court, to have given him such examination, and by his rejection to have prevented an unqualified person from practising on his Majesty's subjects?

But once more: it is required that candidates be young men of "*good moral character.*" Now how, in the name of common sense, can we suppose a young man who is guilty of a falsehood to be a young man of "*good moral character?*" and in what light must we view that set of men who oblige this young man to get an instrument of this

sort (if a necessary one) without making both him and his supposed master guilty of a crime little short of perjury?

From these inferences, then, we may learn that there must be some cause operating at the bottom; but can we really suppose these impartial examiners guilty of trifling, or (to use a commonplace term) of getting up a job? If their object in petitioning the legislature for the Act of 1815, was the amendment of medical science, it was praiseworthy; but viewing the afore-mentioned abuses, suspicion says, was it really so?—No. The Act was thought of in 1812, when a meeting was called to consider the high price of glass; and one thing led to another, until the grievance that they could get no premiums with their apprentices was thought of! A nice hit for making an addition to their incomes! and now they find the thing takes, and that apothecaries flock in abundance to London annually, we are told they are going to do away with the five years' indenture, and substitute a four years' course of instructions; that is to say, they must be two years at the hospitals, and two at play, instead of one at school, and one at play, as heretofore; or else, that we will make the profession respectable by keeping it select, and that by raising the attendant expenses. But if the conduct of these sapient dealers in drugs and diplomas was straightforward and honourable, what occasion for this round of chicanery? if they think a year at the hospitals and lectures, and one at play, has been found sufficient for all the purposes required by their statutes, why are they going to alter it? And why not give an examination to all who apply? If the examination is impartial, every one will then have a fair chance, and there will be no cause for complaint, for it will thus give those whose circumstances have been unfavourable in early life an opportunity of following their inclinations, whilst at the same time the public mind will remain sufficiently convinced of the necessity of a regular apprenticeship for those who begin young.—I remain, sir,

Respectfully yours,
Z.

Kent, May 30, 1833.

ANALYSES AND NOTICES OF BOOKS.

“ L'Auteur se tue à allonger ce que le lecteur se tue à abrégier.”—D'ALEMBERT.

The Transactions of the Provincial Medical and Surgical Association.
Vol. I. 1833.

OF the history and general circumstances of this volume, we gave some account in our last number but one: we have now only to introduce it somewhat in detail to our readers, by noticing a few of the papers which it contains. And we shall begin with

A Case of suspected Poisoning by Cantharides. By DR. HASTINGS, of Worcester.

The author prefaces his narrative with some sound remarks on the importance of legal medicine, and the awful responsibility which attaches to medical witnesses who are called upon to give evidence in matters of life and death. In the following case, it was only by much patience and diligent research that an opinion was arrived at sufficiently convincing to obviate all suspicion of foul play.

“ Miss A. B., aged 32, was governess in the family of a farmer at D., in the county of Worcester. In this situation she had resided for three years, excepting that for six months of that time she was confined in prison, for a pecuniary demand incurred some years before. This naturally had affected her spirits, and, it is not improbable, may have tended to produce some affection of the heart.

“ It appeared, upon inquiry, that Miss B. had never been in very stout health, having been subject to indigestion, and a train of nervous symptoms often connected with that state.

“ For six weeks before the fatal attack she had been more than usually unwell, and was subject every morning to vomiting, and sometimes to pain in the head. About a month previous to her death she went to Kidderminster, to pay a visit to her family; and she was there so ill, that she consulted a medical gentleman on the 24th of December, 1832. From the statement of that gentleman (which he had the kindness to send to me), it appears that the most troublesome complaint at that time was a vesicular eruption, which affected principally the hands and the bend of the arms. The bowels also were very

costive. He prescribed for the young lady an active aperient of calomel and colocynth; and afterwards a powder of hydrag. c. creta and rhubarb, every other night; and a mixture of tartrate of potash and syrup of rhubarb, to be taken twice a day. She expressed herself relieved by the above plan, which did not, however, act sufficiently upon the bowels, and he therefore ordered the following:—

“R Magnesiae Sulph. ʒij; Magnesiae Calcin. ʒij.; Tinct. Sennae fʒss.; Spir. Aetheris. Nitr. Spir. Cinnamomi aa. fʒij. aquae purae fʒvij. M. fiat mistura, ejus sumat coch. ij. ampla bis die.

“The patient derived so much benefit from this mixture, that, after taking part of it, she desisted; and said she would put aside the remainder till she was again unwell.

“This is the mixture which was again taken by the deceased at the time of her last illness, and is alluded to by the witnesses. It is right to state that the young lady bore the highest character with her employers; and Mrs. P. particularly stated, that, excepting her visit to Kidderminster, she had scarcely been out of the house for several months. It was known to the family with whom she resided that she was attached to a young man who lived at a distance, but she scarcely ever saw him, and certainly had not been in his company for several weeks.

“It did not appear that the young lady had manifested any desponding forebodings, or been out of spirits. The duties that she had to perform, in teaching the children of the family, never appeared irksome; and, although not very well, she had not shewn any marks of being particularly fatigued by the engagements that devolved upon her; so that until the day of the fatal attack, no particular notice was taken of the state of this unfortunate lady. Indeed, on the Friday night, January 18th, before being taken worse, she retired to rest tolerably well, and according to the evidence of the young person who slept in the same room with her, she had a very good night, and made no particular complaint early in the morning; but before breakfast on Saturday, whilst dressing, sickness came on, with uneasiness in the stomach. This was not regarded, and she went down stairs, and attempted to take some breakfast; but the attempt was followed by very severe vomiting; and from that time there was no respite from severe attacks of vomiting, and from pain in the back. Still, however, the symptoms were not considered sufficiently alarming to induce the family to send for medical aid until the Tuesday

night following, January 22d. Mr. M. then saw the patient, and found her labouring under incessant vomiting, great thirst, pain in the loins, recurring with increased severity at short intervals; stranguary, considerable discharge of blood from the urethra; the skin, particularly of the face, neck, and chest, covered with a deep red efflorescence; the lips parched; the eyes red with extravasated blood; the roof of the mouth and the tongue were thickly coated, and the pulse was so small and quick as scarcely to be counted. There had been no delirium; on the contrary, her mind was very composed. She manifested no apprehensions of her situation, but expressed herself deliberately and correctly. She could not account for her illness, and said she was not aware of having taken any thing that was likely to disagree with her. Since the attack, she had taken a very large quantity of various fluids, but every thing returned soon after being swallowed: the bowels had acted only once since the severe symptoms came on. The clitoris was tumid and very painful, so much so that she had repeatedly complained of this symptom to Mrs. P. and now called Mr. M.'s particular attention to it. This combination of symptoms he could not trace to any recognized disease. Pork was the only food she had taken likely to disorder her stomach. This she had eaten of the day before the attack: but this appeared no sufficient cause for so severe an illness. Mr. M. very properly, as the powers of life were fast sinking, did not have recourse to any very active treatment, but endeavoured, by all possible means, to allay the irritability of the stomach. He expressed to the family his great apprehensions for the result, and proposed seeing his patient early the next morning. It, however, was Mrs. P.'s intention to be in Worcester early, and, according to her promise, she brought him on Wednesday morning, January 23d, a report of the state of things, which was favourable. The patient had taken two-thirds of a grain of opium, and afterwards two or three doses of the effervescing saline mixture. Her bowels had acted once freely, and the vomiting had ceased. But whilst Mrs. P. was thus relating what had transpired, another messenger came to say the patient was dead; and it appeared, from the description given, that a convulsion fit, the only one she had, terminated her existence.”

The non-medical evidence, which is given by Dr. Hastings, we think it unnecessary to extract. Suffice it, that nothing transpired to prove that poison had been given. But the postmortem examination, which we subjoin, is highly

interesting and valuable in a pathological point of view.

Examination twenty-seven hours after Death.—The surface of the body had, almost in every part of it, a livid appearance. This was most remarkably observed on the sides of the face, on the neck, on the chest and abdomen, and on the thighs; in each of which parts the body was of a dark mulberry colour. There were, besides, on the arms and forehead, numerous petechial spots. Considerable extravasation of blood was evident on the vessels of the conjunctival coat of the eyes.

In making the incision through the thoracic and abdominal integuments, a very thick layer of fat was observed, and the muscles covering these parts were unusually red.

When the contents of the thorax and abdomen were first exposed, the only thing worthy of remark observed by us was, that the great end of the stomach appeared redder than natural.
